Concerning research, he said that he had an intimate talk during last year with a surgeon from the provinces, who remarked that provincial surgeons no longer looked towards the surgeons of London for new notions or leadership, and the reason given was that little or no original research was being done by the London men. Perhaps, Sir Lenthal Cheatle said, all surgeons had had some such thoughts themselves. Taking the first allegation, that London was losing its surgical leadership because it had few men engaged in research work, that must be due to the fact that, in these days, mere technical ability was not enough to maintain leadership or to regain the lost ascendancy. He who was only a so-called clinical surgeon had lost his position as leader in his profession; he could add very little to knowledge, and could himself acquire little more except added skill in technique. Indeed, without research work there was not much encouragement for him to think at all, and so he had a limited outlook. Every surgeon should conduct some research, however little, in association with his actual operating. As a rule, a man could find time for the things he really wanted to do. He had advised students to start original investigation by cutting at different edges wounds of the skin which had healed by first intention. By studying intently some such subject for six months a student would know more than anyone in his year on that subject. If such a man, in the course of his study, came across such a statement as that malignant ulcers of the stomach commonly arose from simple ulcers, he would not accept it as a fact, but would seek to test the statements on which such a belief was founded. He would then find that ulcers excised under the idea that they were simple were really extensively carcinomatous, and that ulcers reported upon as early carcinomata were simple ulcerations in which epithelium was dislocated. There was no pathological evidence that malignant ulcer of the stomach was a complication of a previously simple one. Research work perfected a man's data and led others to perfect theirs; it also kept the mind young, and supplied a constant inspiration, as well as supplying facts and notions not to be found in books. An instance of this was the research of Prof. C. L. Bagg, of New York, who took a healthy strain of mice and mated them, and immediately on the birth of the litters separated them from their mothers so that they could not suckle, then re-mated those mothers, and their next litter was treated in the same way; 87 per cent. of those mothers developed fulminating carcinoma of the breast, and the same result followed ligation of the mammary ducts on one side (the litter being allowed to suckle from the other side), the carcinoma appearing in the ligated breasts. He thought the experiment may have proved that there was another factor essential to the organism than Gye's specific factor—namely, the preparation of the epithelial cell—or it might be that the specific factor had been made more active. He said he considered the term research covered any means by which one strove to add to knowledge of the cause, prevention, and treatment of disease, and he urged, as he had done on former occasions, a much closer collaboration between the clinician and the specialist. The great hope for the future lay in the encouragement of research by the unit system of teaching. Money could not subsidise genius, but he thought it would create a body of men more capable of leading in their profession than any who had existed in the past, and, in due course, genius would come along. The surgeon should always have a skilled assistant available; at present his assistant became skilled when he was due to leave, and a novice took his place, and the same process was repeated. Yet a skilled assistant meant halving the time of an operation and lowering the mortality. The director of a teaching unit should be allowed to have private practice; it would render him a more human and tactful soul, make him a better teacher and operator, and give him a better conception of a surgeon's duties.

Specialties.

Dealing next with specialties, the President said that a further cause of the atrophic state of surgery was the breaking up of this practice into various and completely unnecessary specialties—a system wrong in principle and profoundly wrong in practice. Nature did not specialise, and specialists often lost sight of great guiding principles. The problems of infection, tumour formation, and biochemical changes concerned all parts of the body, and exclusive attention to a small part of the body precluded attention to other tissues as well, unless several specialists acted in conjunction. Already the rigid confines of specialties were being broken down; modern gynæcologists operated on everything connected with the female, except a cerebral lesion, and the laryngologist was now including in his purview extralaryngeal conditions such as goitre, carcinoma of the tongue, and glands of the neck. He would like a means to be discovered whereby this separation of the specialties might be stopped, and he would be glad to see new facts and interests propounded to the whole of the Royal Society of Medicine, whoever the specialists might be who could bring such facts forward.

Treatment.

His last heading, Sir Lenthal Cheatle divided into qualified and unqualified. With regard to qualified practice, he said there was a great and increasing demand on the part of the public for surgical aid near at hand, especially for acute cases, while the body of patients suffering from surgical disorders which were not acute was so enormous that it could not be dealt with in the great centres. Hence large suburban hospitals had been built, and these were staffed by surgeons of first-rate calibre, and they could no longer be regarded mainly as nurseries for men whose ambition was to become attached to the staff of their teaching hospital and school. The men at the outer hospitals must be competing with the teachers and practitioners in the centre. The old system, he said, was really obsolete, and unfortunately the "old" system was the present one. The kudos attaching to a surgeon on the teaching staff, considerable at one time, was now insignificant. The idea seemed to be, "If you teach our students, you shall not run a private practice." It was the younger teachers who were feeling the effects of the decentralisation. And if the best men were prevented from teaching, what would become of efficient teaching? The demand for efficient teachers could only be met by offering high salaries. The problem could only be solved by Parliamentary action, by a controlling Ministry of Health which must be quite free from political fetters; he was not referring to a body such as the present Ministry, which was so hampered by political lumber that it had little or no time to devote to the problems of public health. The headship of it should not be a prize bestowed on a politician for services to his party.

His own views on unqualified practice, he said, were well expressed in the recent presidential address of Sir Holburt Waring to the Medical Society of London, but the condition of affairs revealed in the discussion on that address could not have occurred if a carefully selected doctor had been head of the Ministry of Health.

Prof. C. C. Choyce proposed and Prof. C. A. Pannett seconded a cordial vote of thanks to the President for his address, both expressing general agreement with its main theme.

SECTION OF EPIDEMIOLOGY AND STATE MEDICINE.

A meeting of this Section was held on Oct. 23rd, Dr. J. McVail, the President, being in the chair.

Dr. T. Stacey Wilson opened a discussion on the management and treatment of

Scarlatinal Epidemics in Boarding Schools.

He said that his 25 years' experience in the Royal Institution for Deaf and Dumb Children at Edgbaston led him to class the difficulties of recognition under two heads: (1) Where the patient had only very slight initial symptoms, and (2) where he had no initial symptoms at all, desquamation being the first sign of the illness. Both classes were highly contagious. A child might show nothing but an attack of vomiting or slight pyrexia and yet infect everyone with whom he came in contact. The epidemic was very persistent and would run on for three months in spite of every effort to stop it. It was not always possible to isolate incipient cases, for the only symptom might be a slight flush on the skin of the thigh. This flush might spread or alter its position from day to day or might be gone altogether in 12 hours. The patient was fairly certain to show peeling after a fortnight or so. Although it was not generally accepted, his experience amply proved that many patients showed no symptoms at all before desquamation. In an epidemic that had broken out in the middle of the term he inspected the hands and feet of all the children and found a girl with typical desquamation but no symptoms whatever. He suspected her of being the original cause of the outbreak and one child infected by her died. He had sent 30 or 40 such cases to the fever hospital in the course of 25 years. The difficulties of diagnosis were illustrated by his experience on one occasion when he isolated six or eight children with typical scarlatinal roughness of the hands and feet, and a few more with roughness that he thought was not scarlatinal; of the suspects not one broke out but two or three of the others did. When he said that some cases had no rash at all he admitted the possibility that there had been a rash too slight to attract notice, but since noticeable rash was always attended by symptoms such as sore throat, pyrexia, and a fever-tongue, he thought it legitimate to infer that when these symptoms were not present there was no rash. These patients with no symptoms constituted the chief difficulty in managing the epidemic.

Types of Desquamation.

The disease was often so mild that it only caused exfoliation where the skin was very thin, as between the toes or on the division between the hard and soft skin of the feet and hands. Even in these places the friction of clothes, &c., was likely to destroy the evidence. Since the feet of many people were in a constant state of desquamation diagnosis could not depend entirely on this sign. The true eruption was punctiform, the epidermis broke over small areas, an eighth to a twelfth of an inch in diameter, making small rings or blisters which expanded and became irregular and ragged at the edge. The presence of two or three of these rings was strong evidence of scarlatina. It was important to remember that where skin had become sodden through washing circular breaks might appear in normal people. If these did not increase in size they were not scarlatinal. The appearance of fresh circles between the toes on successive days was fairly good evidence of the disease. Sometimes these eruptions were only visible immediately after washing the feet, and were often so evanescent that only a weekly examination would detect them. If 160 children were examined simultaneously many would have to sit about with wet feet for 20 minutes, which was apt to produce the spurious desquamation described above. Some children became known in time for a chronic spurious desquamation, the rings of which did not increase in size. The edges of the scarlatinal rings did not get dirty but always showed a border of white. (He then showed a most interesting series of photographs prepared with great care by one of the assistant masters which illustrated several types of true and spurious desquamation.)

Discussion.

Dr. E. W. **Goodall** remarked that, for purposes of observation, an institution such as that in which Dr. Stacey Wilson had gained his experience had the advantage over a fever hospital that the population was fixed, while that of the hospital was constantly shifting, and no patient could be watched continuously for months, or even for weeks. It was true that scarlet fever had long been known to occur without a rash, and he admitted that it was much the most difficult of the fevers to diagnose. He would far sooner have to diagnose a case of small-pox. Not a single symptom was characteristic and every one might occur in some other disease; diagnosis had to depend on a combination of symptoms. Some of the severest cases had no rash and were only detected after they had caused an outbreak of scarlatina in a diphtheria ward. Desquamation might be caused by the pressure of the bed or the clothes. In spite of what Dr. Stacey Wilson had said, he maintained that there was no typical desquamation in scarlatina. He had once thought that the pinhole form was typical, but had since seen it in an enema rash, an antitoxin rash, rubella, measles, and even in a rash caused by rubbing with camphorated oil. The disease might even occur without any desquamation; the more brilliant the rash the more liberal the peeling. The strawberry tongue was far more a sign of measles than of scarlatina. So untrustworthy a sign was desquamation that no patient in the North-Western Hospital was ever placed in a scarlatina ward without a period of isolation. He had once admitted a case with liberal desquamation of exactly the scarlatinal type; the peeling was due to a scald some days old, but the patient contracted scarlatina in the ward and died. A true scarlatina case had developed acute nephritis three weeks after a slight rash had broken out, showing that the required period of isolation was sometimes very long. He remarked that Dr. Stacey Wilson's inspection, thorough though it was, did not seem to have cut short the epidemic. He also questioned very strongly whether desquamation was really infectious in itself. The infection was surely spread, not from the peeling skin, but from the mucous membranes of the throat and nose. The returned case-rate had not gone up since he began to send out large numbers of children still desquamating. Perhaps the Dick test and other new methods would help to cut short epidemics.

Dr. F. M. **Turner** remarked that another cause of desquamation was sunburn, especially from intensive sunlight treatment. This caused an erythema followed by peeling very similar to that of scarlatina, so that it was well to inquire if a suspect had been undergoing light treatment. Peeling under the toes was far too general and unreliable to be a sign of scarlatina except to a very experienced observer. A desquamation exactly similar to that of scarlatina occurred occasionally in measles.

Dr. D. **Forbes** said that in school-children where daily inspection was not possible, it was very difficult to distinguish accidental desquamation from scarlatinal peeling, especially if the child were dirty. It was possible for true peeling to become so covered by dirt as to be indistinguishable from spurious. A child was not infectious when peeling unless the throat and nose showed positive signs of the disease.

Sir John **Broadbent** agreed that infection was spread from the throat and nose and not by desquamation. A peeling tongue was a valuable sign after the disappearance of the rash; this never occurred in measles. He described a throat carrier, a child who had had scarlet fever, with headache, vomiting, and sore throat, and who spent eight weeks in hospital, during which time she peeled. Ten days after discharge she went to stay with two old ladies, both of whom developed scarlet fever, one fatally. After a time in a convalescent home the child went home and infected her brother, although she had been perfectly well since she left hospital.

The Dick Test.

Perhaps the Dicks' cultures would help to detect scarlatina carriers as the Schick test detected diphtheria carriers. He had seen cases of bleaching rash detected by the Dick test. When the toxins and their doses had been properly standardised they would be invaluable in testing suspects. A positive reaction would show that the child had never had scarlatina.

Dr. R. A. **O'Brien** said that in his experience the Dick test was not as reliable as the Schick test. Theoretically, the Dick test should give a positive reaction during the first three days of the rash, but in England it had been found that only 70–90 per cent. gave it with 1/1000 toxin. The Dick test would be helpful, in a school like Dr. Stacey Wilson's, in isolating the right children. A child who gave a negative result was almost certain to be immune, though the evidence for this was not quite conclusive. It might be useful to know how soon in an infection a positive Dick reaction became negative. A hæmolytic streptococcus had been isolated from the throat of scarlatinal patients, and he was hopeful that some way of identifying this coccus would be found before long. Gordon's agglutination test for crusts in small-pox had proved of great value, but since scarlatinal skin was now known not to be infectious it was no use there. Possibly some agglutination test might be devised for sputum in scarlet fever.

Dr. S. Monckton **Copeman** said that the disease was much less severe now than when he was a boy. It was much more intense in New York than in this country. The best way of dealing with an outbreak was to carry out the Dick test and immunise susceptible children. A child who gave a negative reaction on admission with a doubtful rash had never caught bad scarlatina in the wards, therefore a Dick negative, although not quite so certain as a Schick, practically meant immunity. A child who gave a Dick negative was not infectious.

Dr. Major **Greenwood** said that isolation measures had not been successful in diminishing the scarlatina incidence; the only hope lay in immunisation.

Dr. T. **Carnwath** said that in Salford cases were discharged after four weeks, sometimes desquamating heavily, and the disease was no worse there than in Manchester where they were kept in six weeks. In Wallasey, where they were only kept three weeks, there were no more return-cases than in other towns. He mentioned a child who had been discharged five weeks and then caught a cold and immediately infected his three brothers. This suggested a latent virus in the throat, liberated by another infection.

Dr. G. C. **Trotter** said that in Paisley they discharged cases after four weeks if they had no nasal or pharyngeal discharge, and had had fewer return-cases than when they kept them in longer. He had known a spurious desquamation caused by playing with lime. Second cases occurring in a family were often missed because there was no system in London by which the second case went to the same fever hospital.

The **President**, in concluding the discussion, said that the malignancy was worse in every way 50 years ago. Hospital isolation had not affected the incidence, but gave the children much better treatment and a better chance of recovery. Future control of the disease would depend on immunisation, but public apathy and dislike of these measures made the work difficult.

SOCIETY OF SUPERINTENDENTS OF TUBERCULOSIS INSTITUTIONS.

Diagnosis and Treatment of Pulmonary Tuberculosis.

AT a meeting of this Society, held on Oct. 19th, Dr. J. W. LINNELL related his experiences at the Victoria Park Hospital, National Hospital, Ventnor, Mount Vernon Hospital (under the late Sir James Mackenzie), London Hospital, and at St. George's Hospital, in coöperation with the late Dr. Arthur Latham. Any value there might be in his conclusions lay in the fact that time had placed them in their proper perspective. As regards general treatment, he considered graduated rest to be more efficacious than graduated labour, and strongly advocated absolute rest in bed for pyrexial cases, his motto being, "Let sleeping dogs lie." He described the tuberculin treatment as practised at Mount Vernon from 1909 onwards. These trials were made for about three and a half years, gradually increasing doses being given subcutaneously and orally, avoiding reaction. It was found that though tuberculin had beneficial effects in cases of tuberculous glands and eye conditions, much the same results were obtained by the injection of any foreign protein. At St. George's Hospital the Spahlinger treatment was tried on specially selected cases. In no pulmonary case did positive sputum become negative; there was no convincing evidence of improvement of lupus after three months' treatment. Surgical cases were equally disappointing. The healing of the ulcer occurred, but the intact nodules were unaffected. This would be noteworthy were it not equally well attained by the injection of either mixed-infection vaccines or peptones. He quoted a case where increasing doses of the latter were administered at weekly intervals to a boy suffering from extensive ulceration of the face and ankles with incredibly satisfactory results. He also referred to his experiences, and their unconvincing results, with mixed-infection vaccines, pneumosan, and intravenous injections of iodoform in ether. He expressed his further disillusionment with Dreyer's vaccine, aurocyanide, and sanocrysin, all of which he had investigated. In fact, he agreed with an eminent bacteriologist who had recently stated that nothing further could be expected from vaccine therapy. Artificial pneumothorax appealed to him as a logical procedure in specially selected cases. Speaking of diagnosis, he urged that all medical students should do "six weeks hard" at a chest hospital before their final examination, and that senior men working in special lines should keep in touch with general work by regular attendance at the out-patient department of a general hospital.

SALFORD ANALYST'S REPORT. — The Salford borough analyst, Mr. S. D. Elsdon, in his annual report for 1924, states that during the year 1700 samples have been submitted for analysis and of these 1544 were taken in connexion with the Sale of Food and Drugs Act, and 156 were submitted by various corporation departments. Of the 1544 samples, 66, or 4·3 per cent., were returned as adulterated, a figure considerably better than that for any year since 1919, when the proportion was 8·8. Of 833 samples of milk, 22, or 2·6 per cent., were returned as adulterated, which figures show that Salford's milk-supply compares not unfavourably with that sold in other districts. All samples of butter examined were found to be genuine, though 18 samples were preserved with boron preservative, equal to 0·3 per cent. as expressed as boric acid in each case. None of the margarine samples was adulterated. Of 55 samples of Cheshire cheese, 6, or 10·9 per cent., were returned as adulterated. Of sausages, in 15·4 per cent. boron preservatives in comparatively large amounts were found. An amount of boric acid which exceeds 2·5 per cent. is undesirable. Of drugs, 10 per cent. were adulterated, chiefly paregoric, turpentine, and almond oil—in the last peach kernel oil being substituted. Of 76 samples of dispensed medicine two were unsatisfactory. In one case the pharmacist was fined, there being a shortage of 20 per cent. of the correct quantity of potassium bromide.

Reviews and Notices of Books.

DENTAL INFECTIONS, ORAL AND SYSTEMIC.

By WESTON A. PRICE, D.D.S., M.S., F.A.C.D. Cleveland, Ohio: Penton Publishing Co. In two volumes. Vol. I., pp. 673; Vol. II., pp. 471.

THESE two volumes of over 1100 pages are devoted entirely to the subject of dental sepsis and its relationship to systemic disease. The book is by far the largest single contribution to this subject and undoubtedly the most important. Though there has been a steady output of literature on dental sepsis since attention was first focused on the subject by Dr. Hunter little more than 20 years ago, we are still far from a complete understanding of the nature of dental sepsis and its results in other parts of the body. Even these volumes, which in their wide scope and thoroughness go far beyond anything hitherto written, still leave the matter in considerable obscurity. They cover a wide field and it is difficult to appraise or even summarise them. Each chapter, or rather essay, discusses a definite problem which is stated at the beginning like a problem of Euclid, and is more or less complete in itself, ending with a brief summary of the evidence. The really remarkable feature of the book is the original investigations carried out by the author. Very many animal experiments have been performed to test the degree of infectivity of organisms from dental lesions under different conditions, and Dr. Price has reached many interesting conclusions. He points out the possible fallacy of judging the degree of dental infection by radiographs. The actual amount of bone-absorption may not be revealed, for it may be concealed by the shadow of the malar bone or hidden by another tooth, or obscured by a more superficial layer of condensing osteitis. He considers that the dental granuloma which so frequently occupies the rarefied apical areas shown in a radiograph, is a defensive membrane which protects the body against the local infection. The protection may sometimes be adequate for a long period. A large area of rarefaction at the end of a tooth may indicate a high defence, whilst an absence of local reaction may indicate a far more dangerous condition. Dr. Price finds that an infected tooth placed beneath the skin of a rabbit tends to become encapsuled and that the membrane round it is histologically indistinguishable from the dental granuloma. It must not be assumed that Dr. Price regards the radiographic evidence of rarefaction as being of negligible significance. What he suggests is that the condemnation of a tooth because of apical rarefaction may not always be necessary, and that the assumption, so often made, that all areas of apical rarefaction represent a serious menace to the general health which is roughly proportional to the degree of the absorption is incorrect. By correlating many factors it is possible within limits to determine the degree of defence of the individual to dental infection. Such infection lowers the ionic calcium of the blood, and the blood-sugar may also be increased. On the question of elective localisation Dr. Price is somewhat guarded, but he finds considerable evidence to support Rosenow's views.

In his second volume he treats of the clinical aspects of focal infection in its relation to diseases of the circulatory, alimentary, nervous, excretory, and other systems. The book is far from being the familiar monotonous record of amazing cures brought about by extraction of infected teeth; the number of cases dealt with is comparatively few, and each one is described in unusual detail. Thus, in a case of myocarditis, not only is the general and cardiac condition fully described, but the dental condition is gone into minutely. The result of inoculation into animals is given, as well as the results of a blood examination before and after dental treatment. This is the ideal method of investigating dental sepsis as a possible cause of a systemic lesion. It is to be feared that it will never become the general method, but the completeness with which Dr. Price has investigated and recorded his cases has provided a most illuminating and helpful commentary. Some of the views put forward are novel and may be regarded as contentious until further investigation has been made; but the value of this book is beyond doubt, and it will probably long remain the fullest exposition of the subject of focal infection in the teeth and jaws —one which no serious student of the subject can afford to ignore. Unfortunately, the extreme length of these volumes may make them a closed book to many. Dr. Price's style is somewhat diffuse and a considerable compression might be effected without in any way impairing the value of the book. The production is admirable and there are nearly 500 illustrations of high technical excellence.

ABDOMINAL SURGERY.

The Early Diagnosis of the Acute Abdomen. Third edition. By ZACHARY COPE, B.A., M.D., M.S. Lond., F.R.C.S. Eng., Senior Surgeon to Out-patients, St. Mary's Hospital, Paddington; late Hunterian Professor and Arris and Gale Lecturer, Royal College of Surgeons of England. London: Humphrey Milford, Oxford University Press. 1925. Pp. 233. 10*s.* 6*d.*

THE fact that a third edition of this little book has been required so shortly after the two impressions of the second edition is proof of its popularity. The general principles of the new edition are the same and but few changes have been made.

The sections on acute pancreatitis and pneumococcal peritonitis have been rewritten, and one of the few errors in the last edition—the statement that the rigidity of the abdomen in cases of acute pancreatitis is more marked than with perforation of the stomach —does not appear. The clinical account of acute pancreatitis is well written and will be helpful to practitioners, but more stress might have been laid upon the fact that the disease occurs in several distinct clinical forms, and too much emphasis is laid upon the presence of a pancreatic tumour and of jaundice. But these are relatively small points. The book as a whole is clear and concise, with useful and practical diagrams.

Chirurgie der Niere und des Harnleiters. By Prof. Dr. J. ISRAEL and Dr. W. ISRAEL. Leipzig: Georg Thieme. 1925. Pp. 584. R.M.36.

THIS is a large book, but it would be difficult to dispense with any of its sections without detracting greatly from its value, for there is an absence of that overlapping all too common in big treatises. Surgical diseases of the kidneys are systematically described, and Prof. Israel gives his views on urological questions with the simplicity that comes from the conviction of truth. An enormous experience has evidently been drawn upon as is shown by the interesting clinical case-histories dispersed through the text. Due acknowledgment is given to workers in countries other than his own. The printing and the illustrations, a number of which are coloured, are excellent. Surgeons engaged in the study of urology will find much of interest in this book.

Pathogénie des Calculs Biliaires et Indications Opératoires. By THORKILD ROVSING, Professeur de Clinique Chirurgicale à l'Université de Copenhague. Paris: Masson et Cie. 1925. Pp. 125. Fr.20.

IN this book Prof. Rovsing is mainly concerned with the causation and treatment of gall-stones. Briefly stated, his conclusions are that they have their origin in the intra-hepatic bile canals and never arise as the result of infection. He thinks it probable that as a result of some transient toxic condition the metabolism of the liver is upset and inspissation of bile occurs; thick soft masses of "calcium bilihumin" are then passed into the gall-bladder, where they serve as nuclei for continuous accretions of cholesterol. The author believes infection to be always secondary to the presence of stones and never their cause. He adduces a wealth of data, both from his own experience and the work of others, but entirely omits to mention one very important piece of evidence in support of his theory, to wit, the almost universal presence of gall-stones—usually unaccompanied by symptoms and in the absence of infection—in cases of acholuric jaundice. Prof. Rovsing is a stalwart opponent of cholecystectomy as opposed to cholecystotomy—he has a disconcerting habit of referring to these operations as "tectomies" and "tomies," respectively—and produces data seeming to show that removal of the gall-sac is no safeguard against the recurrence of gall-stones, and, moreover, providing some grounds for belief that its extirpation may bring about disturbances in the general health. His views are in direct opposition to those of Naunyn, which have gained a wide acceptance: but this acceptance is not quite so general as Prof. Rovsing appears to think. Had Prof. Rovsing omitted polemics from his book, which he might have done with advantage, it would have been considerably shorter and easier to read.

BIO-CHEMISTRY.

Nature of Enzyme Action. Fifth edition. By Sir W. M. BAYLISS, M.A., D.Sc., F.R.S., late Professor of General Physiology, University College. London: Longmans, Green and Co. 1925. Pp. 200. 9*s.*

THIS was the first of a series of "Monographs on Bio-Chemistry," and when it appeared 15 years ago was not a little responsible for the immediate popularity and success of its companion volumes. The present edition was prepared prior to the author's last illness, and we learn from the preface that Sir William Bayliss's daughter completed the corrections after his death. No attempt has been made to add or to remove other than as he wished. It is unnecessary to repeat here what has been said before regarding the clarity of style, the breadth of vision, and the completeness of the material. The subject is treated on the broadest lines, and the detailed description of the properties of a large number of specific enzymes already known finds no place in this monograph, which confines itself to general properties more or less common to enzymes. The reader is given, therefore, a general idea of such properties of enzymes as their physical and chemical nature, methods of preparation, reversibility, mode of action, and so on. Perhaps in a future edition fuller accounts of oxidases and of the glutathione system might be added.

Physical Chemistry, its Bearing on Biology and Medicine. Third edition. By JAMES C. PHILIP, O.B.E., D.Sc., F.R.S., Professor of Physical Chemistry, Imperial College of Science and Technology, London. London: Edward Arnold and Co. 1925. Pp. 367. 8*s.* 6*d.*

THIS book is written with the object of providing the medical and general student with a brief outline of physical chemistry. In this new edition the author has included recent work upon hydrogen-ion concentration, plasmolysis, and permeability, otherwise the general scheme is the same, and in the 14 chapters the reader is taken over the subjects of gases, osmotic pressure, solutions, colloids, and mass action. The treatment is, in every case, clear and explicit; perhaps the best chapter is that on salt solutions, but the exposition of such confusing subjects as specific and equivalent conductivity is particularly lucid. Where all is so good we may yet regret the absence of what might be termed a thermo-dynamic background to the work. Deductions, such as Le Chatelier's theory and Gibb's surface-tension laws, could then have been handled better. There is need for simple, non-mathematical treatment of these subjects, and Prof. Philip is evidently the person to give it. We shall look forward to a thermo-dynamic consideration in the next edition of this useful volume.

ELECTRO-THERAPY AND IONIC MEDICATION.

By HAROLD H. U. CROSS, Ph.D. Med., formerly Research Worker at the Stanford University, California. London: Charles Griffin and Co., Ltd. 1925. Pp. 253. 10*s.* 6*d.*

THIS book is chiefly devoted to the principles and practice of ionisation. Short introductory chapters have been added on high frequency, diathermy, and X rays, and there are also notes on the subject of muscle and nerve testing. The book concludes with a chapter on the electrical treatment of cancer.

The author gives full details for the treatment of suitable diseases by the introduction of ions, and describes some interesting experiments which he has conducted in order to show the migration of metal ions into jelly masses, the depth of penetration being shown by the X rays. His book is written in an interesting and attractive manner. Those who are beginning the study of electro-therapeutics will find a clear and encouraging exposition of the subject of ionic medication, and the experienced reader will find interesting accounts of the treatment of sinuses by a distinctly novel method, and of atony of the uterus by the combined faradic and galvanic currents. He will be surprised to read that the author has obtained good results in the treatment of trigeminal neuralgia by the unidirectional *pulsating* current. It is stated that when solutions for ionisation are being made rain-water or good tap-water can be used, but Dr. Cross insists on distilled water for treatment of wounds or ulcers. Certain statements are somewhat hard to understand—e.g., on p. 95, "The resistance of the tissues is due to their capacity for electro-chemical action more than to mere ohmic considerations." The account of muscle and nerve testing is too short to be of much value, and the definition of partial RD would not be accepted in this country. Nor would the statement on p. 106 that "in cases in which there is no reaction to either current the nerve is evidently divided and surgical interference is required" without qualification and amendment.

SANITATION SUPPLEMENTS OF THE TROPICAL DISEASES BULLETIN.

Supplement No. 2. July 30th, 1925. 3*s.* 6*d.*

THIS supplement contains a subtitle, Applied Hygiene in the Tropics, with the name of Lieut.-Colonel G. E. F. Stammers, R.A.M.C., attached. The supplement covers a very wide range in the headings, including disease prevention, water, food conservancy, small-pox, vaccination, disinfection, child welfare, medical inspection of schools, and industrial hygiene. There follows a section in which reports and vital statistics of various tropical regions are briefly abstracted, and in conclusion several reviews of books on more general subjects. A notice is attached to the Bulletin to say that this series of "Sanitation Supplements" will close with the third supplement, which is to appear on Oct. 30th, and will be replaced by a monthly "Bulletin of Hygiene," the first number of which will be published in January, 1926. This new Bulletin, we are informed, will review in all its aspects the literature of hygiene and preventive medicine with special reference to the needs of the Dominions and the tropical and other colonies and India. Dr. J. F. C. Haslam, late Government medical officer, British Guiana, recently appointed Assistant Director of the Tropical Diseases Bureau, will give most of his time to the Bulletin, and will be responsible for the Section of Applied Hygiene in the Tropics, while for the rest some 35 contributors have undertaken to assist in the provision of material. The subscription rate for the Bulletin will be 21*s.* per annum, and orders may be lodged with the Tropical Diseases Bureau, 23, Endsleigh-gardens, N.W.

JOURNALS.

JOURNAL OF PATHOLOGY AND BACTERIOLOGY. Vol. XXVIII., No. 4. Pp. 541–717. October, 1925.—The Bacteriology of Subacute Infective Endocarditis, by H. D. Wright (London), an important paper which will be made the subject of separate editorial comment. —Effect of Hæmorrhage on the Hæmolytic Titre of the Serum of Rabbits, by J. Mills (Cambridge). Rabbits immunised against sheep corpuscles were bled and the hæmolytic titre of their blood compared with its content in hæmoglobin. The two usually run parallel. Hence, either the tissue fluids from which the blood volume is made up after a bleeding contain no hæmolysin or the capillary wall is not permeable to it.—Complement Fixation with Bilharzia, by N. H. Fairley (Bombay). The active substance in worm extracts is lipoidal not protein in nature.—The Normal Weight of the Human Thymus, by A. B. Bratton (London). See p. 931.—Liver Necrosis and Cirrhosis produced Experimentally by Coal-Tar, by J. Davidson (Edinburgh). Tar painted on the skin or injected subcutaneously in rabbits causes necrosis similar to acute yellow atrophy; this may be followed by cirrhosis.—The Early Phases of Cell Injury, by J. Lorrain Smith and T. Rettie (Edinburgh). Cloudy swelling and necrosis however produced (ether, chloroform, acidosis, &c.) always show first in changes in the mitochondria.—Tuberculous Guinea-pigs and Diaplyte Tubercle Vaccination, by J. S. C. Douglas, J. W. Edington, and F. W. Simson (Sheffield). No effect on the course, extent, or duration of the experimental disease was produced by Dreyer's vaccine.—The Blood Cells of the Rabbit after Splenectomy, by R. H. Mole (Liverpool). Removal of the spleen causes a decrease of red corpuscles followed after several weeks by an increase to more than the normal number.—Observations on the Action of the Convulsant Thujone, by H. Florey (Cambridge). A pharmacological study of the active principle in absinthe.—The Preservation of Testes for Transplantation in Rabbits and Dogs, by N. M. Shustrov, S. G. Karpova, and I. V. Tikhomirov (Moscow). Rabbits' testicles may be transplanted effectively after five days in cold Ringer's solution.—Diphtheria Toxin-antitoxin Flocculation (Ramon Test), by P. J. Moloney and C. B. Wild (Toronto). The Ramon method for titrating toxin and antitoxin in vitro does well for rough tests, but there are many discrepancies between its results and those of guinea-pig tests which it cannot replace. The nature of the flocculation is not understood; it seems to have some relation to the agglutination of the bacilli.—Apparatus for Obtaining Plate Cultures of Anaerobes, by W. J. Wilson (Belfast).—Coliform Organisms in the Trachea, by N. D. Ball (London). Present in 55 of 70 unselected post mortems. Friedländer's bacillus was found eight times; the different strains failed to show any cross-agglutination.—Unusual Serum Agglutination in Typhoid Fever, by J. F. Taylor (London). Agglutinated paratyphoid A to an unusual degree.—Variation in Platelet Count after Splenectomy in Acholuric Jaundice, by S. C. Dyke (Wolverhampton). The rise and subsequent fall in the number of platelets had no relation to changes in red cells or leucocytes.—The Obituary Notices of Deceased Members (12 in number) include Two Interesting Accounts of the Early History of Bacteriology as Notices of Dr. E. Klein (1844–95), by Prof. W. Bulloch, and of Prof. C. J. Salomonsen (1847–1924), by Prof. T. Madsen.—Books received.—Annual indexes.

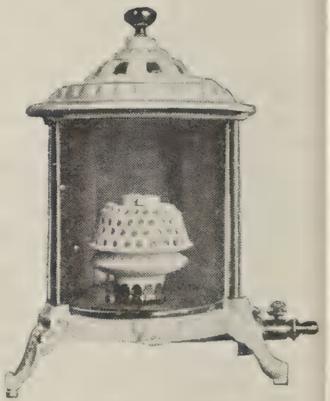
JOURNAL OF PHYSIOLOGY. Vol. LX., No. 3. 1925. The Effect on Muscle Contraction of Sympathetic Stimulation and of Various Modifications of Conditions. By Helene Wastl. The question whether the sympathetic system has any direct influence upon striated muscle has been widely discussed during the last ten years. Many observers who have supported the theory that such influence exists have considered that it consists of an increase of some form of tonic contraction. So far, however, no one has been able to cause increase of muscle tone by stimulating the peripheral end of any sympathetic nerve. Other observers consider that if a muscle is fatigued its activity is more or less restored by stimulating the sympathetic—i.e., that the sympathetic has all the effects on striated muscle that it has on the heart. The author carried out a number of experiments on anæsthetised cats, but no evidence was found that the sympathetic nervous system affects striated muscle, except by modifying the circulation.—The Effect of Changes in Venous Blood Pressure on the Rate of Flow Through, and the Gaseous Metabolism of the Kidney. By E. W. H. Cruickshank and K. Takeuchi. The experiments were carried out on cats under urethane anæsthesia. An increase in the venous pressures in the renal veins produces a proportionate decrease in the blood flow through the kidneys, with an increase in oxygen used per c.cm. of blood. An increase in venous pressure up to 100 per cent. does not necessarily render the kidney anoxæmic ; this is shown by the average figures for oxygen percentage saturation at the end of the experiments—viz., arterial blood 88·8 per cent., venous blood from the kidney, 69·9 per cent. For a certain time, varying from one to two hours, the kidneys under conditions of increased venous pressure amounting to about 50 to 100 per cent. utilise an amount of oxygen per c.cm. of blood, which, in relation to the blood flow, gives a constant utilisation of oxygen per minute.—The Relation of the Thyroid Gland to the Action of Insulin. By J. H. Burn and H. P. Marks. Thyroidectomy diminishes the hyperglycæmic reaction to adrenalin and increases the hypoglycæmic reaction to insulin. Thyroid feeding, so long as the glycogen store in the liver is not diminished, increases the hyperglycæmic reaction to adrenalin and decreases the hypoglycæmic reaction to insulin. When, as a result of prolonged thyroid feeding, the liver glycogen disappears, the hyperglycæmic reaction to adrenalin diminishes and the hypoglycæmic reaction to insulin increases.—On the Effect of Adrenalin on the Respiratory Centre. By Yas Kuno. Adrenalin, as known, produces apnœa by causing complete cessation of respiratory movements. From experiments on rabbits the author concludes that adrenalin does not cause apnœa by constricting the cerebral vessels, but partly by increasing the cerebral blood flow and washing out CO_2, and partly by a direct action on the nerve-cells of the respiratory centre.—On the Production of Anhydræmia with Insulin. By David L. Drabkin. Large doses of insulin in dogs cause a rapid increment in the percentage of hæmoglobin (14·5–44·2 per cent.), a great increase in the cell count, a decrease in the total blood volume, a reduction in the percentage of plasma, and also physical evidence of blood dehydration—increased viscosity and apparent anoxæmia. After large doses of insulin, associated with a rapid, pronounced hypoglycæmia, dogs invariably developed anhydræmia. Unæsthetised rabbits were irregular in their response and were found to be ill-adapted for such a study. The use of "mass" doses of insulin is essential in this type of experiment. The sudden profound hypoglycæmia—the virtual purging of the blood of its sugar—is thought to be the primary cause of the anhydræmia.—The Relation of Ovarian Function to Menstruation. By Wilfred Shaw. After a short account of the work done by other observers, the author describes first his own histological results obtained by the examination of curettings from patients who were menstruating regularly, and from some 40 specimens of the non-pathological endometrium of uteri removed by operation. Evidence suggests that the corpus luteum is responsible for the production of the pre-menstrual changes and of the decidua if pregnancy occurs.—The Relation Between the Size of the Heart and the Oxygen-Content of the Arterial Blood. By K. Takeuchi. It is known that a sufficient degree of anoxæmia produces cardiac dilatation. The experiments were made on cats anæsthetised with urethane and C.E. The chest was opened, artificial respiration maintained, and the inspired air varied in composition in four periods. Cinematograph pictures were taken of the heart beating at each period of the experiments, enlarged and measured in length, width, and area of the hearts. The percentage saturation of oxygen was determined in blood samples taken from the carotid at each period. It was found that the reduction of oxygen in the air breathed produces immediate enlargement of the heart. The readministration produces immediate reduction.—M. L. Anson and A. E. Mirsky contribute two chemical papers, one on Hæm in Nature, and the other on Helicorubin and its Relation to Hæmoglobin. By hæm is meant an iron-pyrol complex associated with a proteid in such compounds as hæmoglobin and hæmochromogen. Hæm is constantly and widely distributed in nature—e.g., hæmoglobin in the blood of all vertebrates—in a haphazard fashion, and a number of natural pigments are related to it. Helicorubin was discovered in 1876 by Sorby in the large snail *Helix aspera*. Its properties, affinities, and composition are described ; its properties seem to be adaptations to the acid medium of the snail's gut in which it is found. Its function is unknown.

The other papers are : The Pulmonary Circulation in the Heart-Lung Preparation (Dog), by G. V. Anrep and E. Bulatao ; The Double Innervation of the M. gastrocnemius, by S. de Boer ; The Effect of Pituitary Extract on the Secretions and Composition of the Urine, by Raymond L. Stehle and Wesley Bourne ; and a description of a new apparatus designed for the study of the conditions of respiration with the chest open, by K. Takeuchi, whereby artificial respiration can be maintained for nine hours or more with the chest open, without producing emphysema and which does not cause more than a trivial decrease in the oxygen saturation of the arterial blood.

New Inventions.

THE LEWCO STOVE.

THIS small circular portable gas stove has been devised for warming a room. The dimensions—12 in. high and a diameter of 8½ in.—allow of it being placed on a table or other convenient place. The external part of the stove is cast iron enamelled ; it is provided with a copper reflector on the base and on half the circumference. The cover can be lifted off, and a heating surface is thus provided which may be used for boiling a kettle. The burner is a truncated cone of fine fire-clay in two parts, and so constructed that the heat is evenly distributed. There is no contact between metal and non-luminous flame. The arrangements for altering the pressure of gas and controlling the entry of air are simple and efficacious.



The stove has been tested by us to see if combustion of the gas was complete. The products of such combustion were collected, and on careful tests being made with blood no trace of carbon monoxide was found. It may therefore be used with safety in a well-ventilated room, always provided that the admixture of gas and air is correctly adjusted. We have here a practical and ingenious piece of apparatus of considerable use for a variety of purposes. The price is 35*s.* complete, in various colours, and it can be obtained from the Provincial Manufacturing Company, 12 and 13, Henrietta-street, London, W.C.

THE LANCET.

LONDON: SATURDAY, OCTOBER 31, 1925.

WALES AND ITS MEDICAL SCHOOL.

As was noted in our columns last week, a further stage in the controversy regarding the government of the Welsh National School of Medicine was reached at a meeting of the Court of the University of Wales at Llandrindod on Oct. 16th, when, on the proposition of Alderman William George, a resolution was passed by 71 votes to 41 expressing the opinion that the School should be constitued as an independent school of the University and resolving that His Majesty in Council should be petitioned for a charter to bring this about.

The controversy is of some standing, and the salient points may not be within the recollection of all. In 1916 a Royal Commission, presided over by Lord Haldane and composed of many distinguished educationists, unanimously recommended that the School should be a separate entity of the University of Wales. This course was not followed, and in 1921 the complete School was established as a part of the University College of South Wales and Monmouthshire at Cardiff, with special arrangements, including the formation of a board of medicine to administer the School under the Council and Governors of the Cardiff College. A draft supplemental charter to ratify these arrangements was submitted by the Cardiff College to the Privy Council, which rejected it, and affirmed the recommendations of the Haldane Commission. As the College did not agree, the Privy Council referred the question to the University, which through its Council recommended a school directly under the University and submitted a draft scheme to the Privy Council. Approval of such a scheme has now been obtained from the Court, the governing body of the University, at its Llandrindod meeting. The advocates of an independent school separated from the Cardiff College contend that thereby the School will be truly national, its prestige greater, its administration simplified, and its financial support larger and more assured. Those against separation from the College point out the advantages to medical staff and students of College association and stress the difficulties of separation as regards land, buildings, and money. A very animated discussion, which lasted most of the day, took place at the Llandrindod meeting. Members of the Court had already received a considerable amount of literature which included, as expressing outside opinion, statements from Sir Charles Sherrington and Sir Thomas Lewis in favour of separation and from Prof. Adami against it. The arguments employed by the opponents to the policy of separation have been summarised in the frank statement circulated from the Vice-Chancellor of the University of Liverpool, and while admitting that on the constitution and conduct of universities he must be considered a first-class authority, we do not find the views of those who think with him broadly correct on general principles. Under the policy of separation it should be realised that the University connexion will be retained. Further, the apprehension that the other constituent Colleges of the University will be led to the burden of starting departments of anatomy and physiology out of rivalry to Cardiff seems to be far-fetched, for the number of students requiring courses on these subjects but not wishing even to enter the medical school of the University can hardly be large enough to warrant any dissipation of energy.

We have nothing but sympathy with the aspirations of Wales to establish a good medical school, and our sympathy is extended also to the Cardiff College which founded the School and naturally desires to keep it. A school of medicine, however, with its associated hospital organisations (and it is to be noted the Cardiff Royal Infirmary is in favour of separation) is too big a thing for a single university college to manage. The opinions and desires of the Royal Commission and Privy Council must carry weight. Association of staff and students cannot be forced; it will come naturally by work in institutions situated side by side. Only by an untrammelled and simplified administration can the School realise itself and develop on the best lines in the future. Granted goodwill on all sides, which should be forthcoming, disentanglement of mutual possessions should be a simple matter, especially as school properties are only held on trust by the Cardiff College and it has no power to deviate them from school purposes. We are of opinion that only by the constitution proposed by the University of Wales will the School undergo proper development and become not only a national but an international institution for medical education and research.

◆

THE ÆTIOLOGY OF ECLAMPSIA.

Physico-chemical methods are continually being applied to the medical sciences, and the harvest which is being reaped as a result of this application is of significantly ingravescent magnitude. It may be regarded as an axiom that every principle involving the inorganic world will ultimately be involved in the attempt at a rational interpretation of the organic. As long ago as 1690 Huygens, when studying the refraction of light through a crystal of Iceland spar, discovered the fact of plane polarisation. Over a century later Arago noticed that when a plate of calcite cut in a plane perpendicular to the axis was placed in the beam of light traversing a path between two crossed nicols, no rays passed the analyser. If, however, a plate of quartz were substituted for the calcite, part of the beam of light was transmitted. Evidently the plate of quartz had rotated the plane of polarisation which had been impressed on the light-waves during their passage through the first nicol. Some substances were found to rotate the plane in a clockwise, others in an anticlockwise direction, and were consequently given the names dextrorotatory and lævorotatory. A more puzzling phenomenon was brought to light when it was found that certain liquids—e.g., turpentine—also produced rotating polarisation and that this power was not lost even when the substance was in the state of vapour. Clearly the phenomenon was one intimately connected with the structure of the individual molecules. Solutions of some substances likewise exhibit this phenomenon, and the fact that the degree of rotation is proportional to the concentration of solute at once gives the possibility of quantitative analysis to this principle. If two or more rotatory substances are in solution together, then the degree of rotation is the algebraical sum of their individual rotations when separately investigated in the same concentrations. The application of these principles, as is well known, has been of great industrial value in the determination of sugar and is also made use of extensively in the estimation of sugar in biological fluids.

We publish in this issue a paper by Dr. Alexander Hynd on some preliminary experiments on the nature of urinary protein, in which the principle of rotatory polarisation is invoked. Some extremely interesting facts have come to light. Investigation of the rotatory power of the urine from a case of eclampsia showed that this was considerably less lævorotatory than would have been expected from the amount of protein present and from the assumption that the protein present was serum albumin. This result led to a more careful and systematic investigation of the rotatory power of the carefully purified albumin obtained from the urines of 12 cases of albuminuria of pregnancy (without convulsions) and of 14 cases of eclampsia. Five cases of proteinuria not complicated by pregnancy were similarly studied. In all the cases of albuminuria of pregnancy without convulsions the specific rotation of the urinary albumin ranged from –48·9° to –65·7°, with a mean value of –55·81°, a figure which agrees extremely well with the mean value of the specific rotation of the albumin excreted by the five cases of proteinuria uncomplicated by pregnancy, viz., –54·27°. Since the specific rotation of human serum albumin prepared by a process exactly similar to that employed in the purification of the urinary albumin gave a value which approximated closely to those given above, one is tempted to conclude that the albumin excreted in these conditions is serum albumin, a tentative conclusion which agrees with the commonly accepted view.

In the cases diagnosed as eclampsia, however, the rotatory power of the urinary albumin is in many instances much below the serum albumin figure and warrants a division of the series into a high and a low rotatory group. The specific rotation in the latter group varied between the limits of –33·92° to –41·61°, with a mean value of –38·5°; that in the former between –49·4° and –58·67°, with a mean value of –56·37°, a figure agreeing closely with that of serum albumin. Dr. Hynd shows that cow's lactalbumin has a specific rotatory power of –41·17°. The figure for human lactalbumin would probably be of like magnitude, and "it would seem," he says, "a significant fact that while in no case of proteinuria uncomplicated by pregnancy, nor in 'albuminuria of pregnancy' *without* convulsions, has an abnormally low specific rotation for the urinary albumin been observed, in a large percentage of the eclamptic cases the albumin excreted in the urine is considerably less lævorotatory than serum albumin. Experiments have been in progress to determine the nature of this low optically active urinary albumin, but owing to the difficulty of obtaining material suitable for such investigation, so far no definite conclusion has been come to, and further work will be necessary. The value of the specific rotation, however, suggests that the albumin may be lactalbumin." If this suggestion be accepted, "we have in certain cases of eclampsia an analogous condition to the lactosuria which not infrequently occurs in the late months of pregnancy or soon after labour, while corresponding to the symptomless albuminurias of pregnancy there exists the fairly common glycosuria of pregnancy. However, while the presence of lactose in the blood and its excretion in the urine would do little or no harm to a patient, the presence in the blood-stream of lactalbumin, which must be regarded as a foreign protein, might entail great danger." The suggestion is tentatively promoted that eclampsia is the symptomatic expression of a supersensitiveness to lactalbumin and is essentially of an anaphylactic nature.

We shall look forward with interest to the results of a more extensive investigation on the nature and origin of the urinary protein in eclampsia, and to the effect which these will inevitably produce on the fascinating suggestions made in Dr. Hynd's paper as the result of his preliminary and carefully conducted experiments

◆

MALARIA AND AGRICULTURE IN BENGAL.

A report[1] to the Government of Bengal, on malaria in relation to agricultural conditions in that province, by Dr. C. A. Bentley, Director of Public Health, raises questions of general interest no less than of vital local importance. The report urges that the Gangetic Delta depends both for prosperity and health on annual inundation, which leaves on the land a deposit of fertilising silt, and hinders anopheline breeding during many weeks of otherwise favourable conditions. Nevertheless the very circumstances which bring richness to the land tend to its decay; for with each annual flood the layer of fertilising silt, while deposited broadcast, yet reaches its greatest depth close to the river banks, so that natural embankments are there formed over which the normal annual flood finally fails to escape. During flooding, silt is also deposited in the river beds themselves, whence however it is ordinarily scoured out, for the now clarified flood water drains back into them as the river level falls. If this process do not occur, such waterways are left, in the dry season, choked, stagnant, and dead. This condition, as would be expected, is most advanced about the apex of the Gangetic Delta where land is extensively derelict, wild and cultivated vegetation indicate soil drought, and malaria is excessive. It is, moreover, held that this natural decay of the Bengal river system is accelerated by embanking the rivers, and is intensified by the building of thousands of miles of raised roads and railways; for—and the point is stressed—embankments of this kind, fallow land, and malaria are all more abundant in Western than in Eastern Bengal; thus it is definitely concluded that such embanking is the cause both of the existing agricultural depression and of malaria. Among examples is cited the Hoogly district, where embankment of the left or eastern bank of the Damodar has prevented the river from spilling eastwards across that district into the Hoogly river, the westernmost of the stream of the Gangetic Delta. Crop experiments have shown that the average out-turn of the rice plant is greater by half when irrigated by Damodar water than when not so irrigated, while the Hoogly district is now one of the most malarious in the province, to which condition is also largely attributable the fact that its population in 1921 was less than in 1872. Further, comparatively healthy Eastern Bengal, which is yearly flooded, has, relative to area, 28 per cent. of the railway and 6 per cent. of the road mileage of the more malarious Western Bengal. It is therefore argued in the report that, to prevent extension of malaria in the Delta, normal inundation must be encouraged by maintenance of channels and spill areas, and by absolute prohibition of all embankments, including those of railways and roads, until these can be constructed without obstructing natural irrigation and drainage. In the meantime the effects of embankments upon the water table should be investigated and a survey should be made of malarial distribution, of agricultural conditions, and of the various water-courses, drainage maps of the district being prepared.

These recommendations lead naturally to a scrutiny of the proffered evidence that embankments of these various kinds have indeed caused the ills attributed to them. That the actual process of embanking may induce temporary malarial outbreaks is unquestionable; that completed embankments have permanently altered the health of Bengal is admittedly difficult to prove, or disprove; but the evidence offered for their harmfulness appears too little convincing. It is, of course, clear that embankments for rivers, roads, and railways will be built preponderatingly upon those upper parts of the Delta which have nearly, or actually, become raised above ordinary flood level, and where flooding is felt to do more economic harm than good. These higher tracts may be taken as evidence that land is permanently emerging from the waters and that hydraulic conditions are being radically altered. It will surely be felt by many, in spite of the facts cited in this Report, that there is still no answer to the following question: "To what extent is this natural alteration, with its concomitant agricultural and hygienic deterioration, aggravated by man's efforts?" There are undoubtedly those who are satisfied that there is another side to the whole question. Witness the Damodar embankment, just cited, and to which the ill-health of the Hoogly district has been referred. No one who has looked out daily for months upon a pleasant midstream island in a big Indian river and has awakened one monsoon morning to unbroken wastes of rushing water—a deep channel where palms and huts stood the evening before—can ever leave out of count the well-established vagaries of rivers on Indian alluvial land; so that it is difficult to reject as ill informed the definitely held opinion that the main current of an unembanked Damodar river, diverted in the usual freakish manner, might readily follow the example of other well-known rivers, scour out one of its numerous spill channels across the few miles of intervening Hoogly district, and enter the Hoogly river above, instead of below, Calcutta. The existing river bed could not hold both waters; the damage entailed to the city and port of Calcutta none can estimate. Bonification, carried to its greatest success in Italy, is defined in the Report as the regulation of all surface waters, the improvement of soil fertility, the cultivation of crops best suited to local conditions, and the increase in numbers and prosperity of the population. Dr. Swellengrebel, in an appendix to the report to the League of Nations of its Malaria Commission upon a European tour of investigation in 1924, describes Italian *bonificazione* as comprising the measures of social hygiene taken to improve the hygienic condition of the inhabitants, to increase their well-being and ultimately their resistance to malaria; sanitary ends are gained by economic measures. He adds, however, that the problem of housing is given constant attention, and that the difference between districts completely "bonified" and those untreated or only partly so was much more evident in the condition of human habitations than in the amount of anophelism, which was not appreciably different. The value of housing is in the forefront of the Malaria Commission's representation. The Commissioners class as "primary," and always indispensable, antimalarial measures those limited to malaria-infected individuals and the houses in which they dwell, and they include among them the discovery and full treatment of all cases of malaria by house-to-house inspection, and the instruction of inhabitants in their homes as to where mosquitoes are to be found, how they are to be caught, discouraged, and repelled.

---

[1] Calcutta: Bengal Secretariat Book Depôt. 1925. 4s.

Full of promise, then, for Bengal, as Dr. Bentley notes, is Rai Gopal Chundra Chatterji Bahadur's movement for the formation of coöperative antimalarial societies; and more than good wishes are his due in an uphill fight. Based largely, no doubt, on experience of Algeria, where a pestilent, avoided region has become a reasonably healthy one of intensive cultivation with scarce room for another blade of grass, as is picturesquely said, the view is becoming evident in French literature that the best way to exterminate malaria is to improve well-being, and that good administration can pre-eminently aid this. It is, however, well to keep in mind the extraordinary effects produced in the Malay Federated States—associated with the name of Sir Malcolm Watson—which have followed intensive study of the conditions which favour the breeding of the particular anopheline species locally implicated in malarial transmission. In agreement perhaps with Colonel Fry's report, written in 1914, that, since all Bengal anopheles have similar breeding habits, identification of the species acting as optimum host is merely of academic interest, the present report holds no mention of "species sanitation." It is becoming widely held elsewhere that identification of implicated species promises well for future preventive work. No later work on these lines than Fry's is traceable in Bengal, and it is difficult to believe that species with identical habits are implicated in the different conditions of Western and Eastern Bengal. Fry dealt only with Western Bengal and wrote "It would appear that different factors concerned in malaria production and maintenance . . . inextricably overshadow each other." It follows that only by future patient extrication of the tangle can that scientific lead be given to the administration without which its efforts at social and hygienic amelioration must prove risky, expensive, and, not improbably, futile.

SURGICAL DEVOLUTION.

In his Presidential Address to the Section of Surgery of the Royal Society of Medicine, which we report on another page, Sir Lenthal Cheatle was both stimulating and inspiring. He took for his text the thesis: Surgeons in London are in danger of losing their place as leaders of surgical thought—and, without affirming or denying it, he admitted danger and suggested how to meet it. Real leaders in surgical thought are necessarily few in number and they may crop up anywhere. The London routine of surgical training can hardly alter one way or the other what is essentially a biological phenomenon, but Sir Lenthal Cheatle touched the spot when he said that the leaders of surgery, if they are to lead, must always have before them the ideal of investigating. Surgical technique in particular cases—e.g., appendicitis—has been developed to such a point that nine out of ten patients can be operated upon nearly as efficiently by the less experienced as by the more skilled surgeon. Much of what may be called routine surgery is done in present circumstances by operators in outlying districts who may be general practitioners. This is the natural result of the opportunities for surgery offered in the schools to house surgeons and others, but the operating practitioner does no more than follow accepted surgical teaching. Leadership involves work on problems more difficult than these and something more than mere technique. The surgical leader must be a thinker and an investigator. Sir Lenthal Cheatle believes that surgical specialisation has been carried too far, and in this he has the support of a brother-surgeon who holds that patients should only be segregated out of the general surgical ward so long as interest is focused on the particular region or the particular morbid condition; investigation being complete and the lines of treatment settled, they resume their beds in the general ward. The good general surgeon is probably now in every way as good as he has ever been, and it is not difficult for him to acquire some special things, such as cystoscopic technique, whereas the specialist can only extend the area of his special subject with difficulty. Happily, the standard of work at a teaching hospital is constantly kept up not only by the collaboration of colleagues, but by the insistent criticism of students. The surgeon, like any other craftsman, may be inclined to magnify the importance of technical ability, and technique is more important in surgery than it is in any other faculty, but the judgment born of experience and wide contacts is as important for the right handling of the individual case as it is for the advancement of the science. One who is only a clinical surgeon and nothing more cannot hold a position as leader in his profession. We are sure that Sir Lenthal Cheatle's address will do good. He has put into measured words thoughts which have been exercising the minds of surgeons for many years past, and if his remarks should lead to some searching of heart, nothing but good can come from it.

◆

AN ENCYCLOPÆDIA OF INDUSTRIAL HYGIENE.

The first two brochures have reached us of the "Encyclopædia of Industrial Hygiene," which is being brought out under the title Occupation and Health by the International Labour Office at Geneva. The object of the work is to disseminate as widely as possible the information required for the detection of occupational diseases, to indicate the steps to be taken for their cure and prevention, and to lay down general principles for the better protection of the workers. It is intended not merely for industrial physicians, who must find it a standard work of reference, but for workers, manufacturers, and their organisations. Consideration is given to the work, the worker, and his environment. The work is analysed according to process and risk. The worker is envisaged in relation to the products with which he is in contact. Environment is concerned with such matters as ventilation, lighting, dust removal, and sanitary accommodation. The importance of such an international publication can hardly be overestimated to-day, when matters of industrial legislation, aimed at establishing health in occupations, are so much to the front in every civilised country. The list of expert collaborators who are engaged upon its production, chosen from France, Britain, Austria, Belgium, Germany, Italy, United States, Switzerland, Holland, Sweden, Spain and Poland, is sufficient to vouch for the authenticity of the articles which are all submitted for comment to a correspondence committee before issue. The encyclopædia is appearing in two languages, French and English. The first two brochures contain 12 articles dealing with definite industrial poisons, such as mercury, carbon monoxide, phosphorus, and benzene; one concerned with hatters furriers' processes is well illustrated, and each contains a useful bibliography. The price (£1 12*s.*) charged for the total issue, which promises to be an extensive work, is such as should appeal to a wide circle of readers. We tender our congratulations to the International Labour Office for undertaking this useful and important piece of work.

Annotations.

"Ne quid nimis."

THE ECONOMIC ASPECT OF SMOKE.

At the Plymouth Gas Conference on Oct. 21st Dr. R. Veitch Clark, medical officer of health for Manchester, made an important pronouncement on the conservation of human energy from the point of view of smoke pollution. The gloom which envelops the great industrial belts of England and Wales during the winter months is due very largely to pollution of the atmosphere with the products of combustion of raw coal, and even in the height of summer the Manchester sun records only slightly exceed the winter records of such places as Southport, Brighton, and Eastbourne. Dr. Clark does not claim that the abolition of the smoke evil will abolish even one disease, but he does insist that it will greatly diminish the incidence of disease and produce enhanced efficiency in adult life. There are few who do not react to the depression of atmospheric dinginess, and the Industrial Fatigue Research Board has demonstrated the diminished output of work when lighting conditions are bad. Dr. Clark, as did our Berlin correspondent last week, drives his attack home through the atmospheric envelope to the personal envelope, remarking that ultra-violet rays will not pass through clothing. He regrets that man, particularly male man, does not adapt his costume more sensibly to climatic conditions. Prof. J. B. Cohen and Dr. A. G. Ruston, in a new and enlarged edition of their book on "Smoke,"[1] think that the effect of smoke on health will have to be clearly proved before the Ministry of Health, for example, will take any steps. Without entering into the question of health, however, save to include a rather unsatisfactory appendix containing certain statistics by Dr. Ascher, of Hamm, Westphalia, these authors have brought forward a startling indictment of smoke in their account of the ravages for which it is responsible on vegetation, metal work, and masonry. The fact that the crumbling of the House of Commons is due to the effects of products of inefficient combustion of coal in London air may perhaps bring legislation a little nearer. Domestic soot is particularly deleterious in its effects on vegetation, for the high percentage of tar it contains makes it more adhesive, and soot affects the growth of plants by blocking up the stomata and impeding transpiration, by reducing the intensity of sunlight absorbed by the leaves, and by the corrosive action of the acid it contains. The effect of soot on crops has been studied both in the laboratory and in carefully planned field experiments. One crop of lettuces, for example, grown in the centre of the industrial part of the city of Leeds, was only a quarter of that obtained in an outlying agricultural area. By special methods these authors showed that the smoke cloud over the industrial part of Leeds shuts out 40 per cent. of the daylight, and with regard to the effect of soot on the laundry bill they quote figures which indicate that a big town in the north of England would save about £250,000 a year in household washing expenses if only the city smoke were eliminated. The deleterious effects of smoke on masonry and metal work are due principally to the presence in the air of towns of sulphuric and sulphurous acids derived from the coal. The action of such acids upon all stones having lime or magnesia in their composition is rapid and progressive. Striking illustrations of this are shown in this book, including photographs of portions of the masonry of certain public buildings. In this connexion Sir Frank Baines has asserted that H.M. Office of Works would save at least £120,000 per annum if the air in towns were as clear and as pure as in rural districts.

---

[1] Smoke: A Study of Town Air. New and enlarged edition. London: Edward Arnold and Co. 1925. Pp. 108. 8*s.* 6*d.*

Prof. Cohen and Dr. Ruston have certainly collected an imposing list of crimes for which smoke is responsible, and it is surely a matter which affects the public weal so closely that interference by the authorities, even although this means tampering with the home fires, would be a thoroughly justifiable procedure. Dr. Cox has, however, been quoted as saying that it may require the death from fog of three Cabinet Ministers before any action is taken.

PROGNOSIS IN BILATERAL BREAST CANCER.

WE reviewed last week Mr. Grey Turner's incitement to encouragement in cancer surgery, and no one reading his book can take a gloomy view of surgical intervention for tumours in many localities. There is a widely held opinion that when cancer involves both breasts the prognosis in regard to cure, or even marked prolongation of life, by operation is almost hopeless. This outlook is combated by Dr. Clarence A. McWilliams,[1] who records the results in 98 cases of bilateral breast cancer, of which 87 cases had cancer developing consecutively and 11 cases in which cancer developed simultaneously in both breasts. He calculates, from grouped statistics, that of patients with operable cancer in one breast 5 per cent. will develop cancer in the remaining breast. Of the 11 cases of simultaneous cancer only one lived longer than four years after operation. But of the 87 consecutive cases 54 per cent. after the first operation and 24 per cent. after the second operation lived for five years. McWilliams considers, from these figures, that in the simultaneous cases the prognosis is practically hopeless, but in the consecutive cases very fair. In the consecutive cases he regards the growth in the second breast as primary, and not an extension or a metastasis from the growth in the first breast, and gives good reasons for his belief.

NATIVE DIETS.

THE problems of diet are still very much under discussion at the present day, and among the many theories put forward to explain this or that defect in the health of civilised man is the superficially attractive one that his diet has also become much too civilised. The alleged freedom of the primitive tribes from cancer, for example, is ascribed by enthusiasts variously to their simple foods, to the small amount of cooking employed, or to the absence in certain cases of meat in their dietaries. In this respect information as to what the primitive tribes actually do eat and what effect, if any, their diet has upon their general health and well-being is certainly needed. A recent discussion on native diets reported in the *Kenya Medical Journal* (August, 1925) brings out many interesting points. Dr. C. J. Wilson, who opened the discussion, attempted to answer the two principal questions brought up by this subject—namely, What do the natives of Kenya eat? and What ought they to eat? The natives in the reserve live upon a diet described as being on the border-line of food deficiency, being preponderant in carbohydrates with meat in some form as, at any rate, an occasional part. Such a low diet appears to render the native more susceptible to disease than the well-nourished individual and unable to cope with hard manual labour. In connexion with the Carrier Corps (the native labour employed during the war), in certain of the native prisons and with some business concerns employing native labour, actual diets have been worked out and adjusted so as to get the best results. One such diet which proved very satisfactory consisted of 2 lb. of mealie meal daily, 2 lb. of chiroko beans weekly, 2 lb. of meat weekly, and one lemon weekly. The difficulty facing anyone dealing with natives whose staple food consists largely of maize is to get sufficient protein of biological value into the daily diet since the proteins in maize are very low in the scale—2 lb. of maize, for example, contain excess of carbohydrate and only about half of what is conceived to be the minimum amount of protein according to European standards. The difficulty immediately arises that most of the known facts on diet have been worked out on Europeans or Americans. Does the native need meat? In the opinion of one of the subsequent speakers all the tribes need meat if they are going to keep fit for hard work, and he quoted in support of this contention the fact that a certain company giving the diet detailed above to the natives in its employ was quite sure that "their boys worked better with it." Another speaker stated that every contractor for some railway construction work "gave his boys meat because it cheered them up," and on a liberal diet containing meat there was stated to be an improvement in health and in capacity for work. It may be argued that the diet to which a native is accustomed is the best diet for him, but the experience of the acting Chief Native Commissioner, Colonel Watkins, who took part in the discussion, was that the native must be trained to take a better diet, for this, it was urged, would make him more adaptable to changes in surroundings and climate and more resistant to disease. The Chairman, closing the discussion, brought forward some significant figures which showed that on a rough estimate the result of an improved diet at a Carrier Corps hospital was to lower the death-rate from 33 to 3 per cent. It will be interesting to see if the improved diets of the primitive tribes will in any way approximate to the simple diets to which civilised man is sometimes advised to return.

THE TARGOWLA REACTION FOR SYPHILIS.

MOST of the modifications made in the original technique of the Wassermann reaction have had simplification as their object, but even the simplest of the reputable variations is beyond the time and experience of the general practitioner. If, then, a simple test for syphilis could be found its value for the busy practitioner would be great, but though there have been many such suggested they have all been rejected as useless. The reaction introduced by Targowla in 1923 did not apparently receive much attention in this country, but an investigation of its value in 200 cases of syphilis by Bernard and Ruelle[1] has produced some striking results. This reaction depends upon the curious fact that mixture of normal cerebro-spinal fluid and "elixir paregoric" produces a colloidal suspension, while with certain pathological fluids a precipitate is formed. The "elixir paregoric" of the Belgian Pharmacopœia contains tincture of opium, 50 g.; benzoic acid, 5 g.; camphor, 3 g.; anethol, 2 g.; and 70 per cent. spirit, 940 g. Fifteen drops of this are mixed with five drops of water and 15 drops of cerebro-spinal fluid in a test-tube, while a control tube contains 20 drops of water and 15 drops of elixir. At the end of 24 hours there is either more or less precipitation in the first tube (a positive reaction), or no precipitate at all (a negative reaction). The positive reaction is said to be given in cases of cerebro-spinal syphilis and in disseminated sclerosis only, and in 100 cases investigated by Targowla the parallelism between this reaction and the Wassermann reaction was complete in 91 cases. In six of the remainder, all cases of undoubted syphilitic infection (general paralysis, meningitis, and congenital syphilis), the Targowla reaction was positive and the Wassermann reaction negative. In the other three cases the Wassermann was positive and the Targowla reaction negative. Bernard and Ruelle investigated this reaction on 200 cases of syphilis in all its stages, and found that the results of the Wassermann and the Targowla reactions were discordant in only 28 cases. In 14 of these the Targowla was positive and the Wassermann negative; all but three of these 14 cases had definite symptoms and signs of cerebro-spinal syphilis with a history of infection. Of the other 14 cases, which gave a negative Targowla and a positive Wassermann, nine were cases of general paralysis or tabes; one had suffered from an acute syphilitic meningitis (during which time the Targowla reaction was positive), while the four remaining were without any signs or symptoms whatever. These authors therefore claim that not only is the parallelism of this simple test with the Wassermann reaction sufficiently striking to make it of great value, but also that in cases of cerebro-spinal syphilis other than general paralysis or tabes it is actually even more reliable. Difficult biochemical and pathological problems immediately arise if these results can be repeated by other observers, but the very simplicity of the reaction certainly seems to warrant its close investigation in this country.

DENTAL PROPAGANDA.

THOUGH pain will often recall the prodigal patient to his dentist, the population at large suffers dental disease more or less gladly because it produces no discomfort comparable with the harm it is causing. The insidious nature of the damage gives a real and special importance to public instruction on the care of the teeth. What form this propaganda should take may be in question, but the necessity for it is beyond doubt. In an address on the subject at the British Dental Hospital on Oct. 15th, Dr. James Wheatley rightly laid more stress on the cultivation of hygiene than on preventive dentistry, and emphasised the need for providing an incentive to right living as well as instruction on how to achieve it. Knowledge is one thing, conduct is another. In particular, he believes, it is necessary to find an incentive for the adolescent who has thrown off the control of parents without accepting the bonds of purpose or of any real object other than pleasure. To excel in sport and to excel in beauty are aims which can be legitimately exploited, and it must be more generally realised that health is a thing to be proud of and that disease is usually the reverse. The ambitious scheme for widespread propaganda put forward by the Dental Board has already been described in our columns.[1] Dr. Wheatley welcomes the action of the Board as likely to educate the public in oral hygiene, but is concerned that it should fit in with the general scheme of public health education. The influence of the Board might be very valuable in a central propaganda organisation loosely attached to the Ministry of Health which should coördinate and assist the work of the health services and voluntary organisations; but in direct public propaganda its influence would be less useful. Dental propaganda, he considers, should be an inseparable part of general health propaganda; it must continue over many years and can only be effectively undertaken by those bodies which have access to the homes and schools. Its presentation to the public depends as much or more upon understanding the mental capacity, attitude, and general environment of the people approached, as upon a complete knowledge of the science, and advocacy of dental treatment is less likely to be suspect to the more ignorant section of the population if it does not come directly from the dental profession. Dr. Wheatley again drew attention to the significant fact that after 50 years of universal education 20–70 per cent. of parents refuse skilled dental treatment for their children when it is provided free of charge, and he suggests to education authorities that they should look upon acceptance or refusal of dental treatment as evidence of the true success or failure of the education in their districts.

A MEXICAN PUBLIC HEALTH BULLETIN.

THE appearance of the first number of what is intended to be a quarterly Bulletin[2] affords satisfactory proof of the intention of the present rulers of Mexico not to lag behind the rest of the civilised world in matters of hygiene. If the programme outlined in this volume is effectively carried out, no easy task in a country with such a turbulent population, it will be a great achievement for the Government, and in any case is evidence that in the matter of public health they have high standards before them. With a view to greater efficiency, the department seems to have been more or less reorganised at the beginning of this year, and now consists of the following sections: Infectious diseases; disinfection; tropical diseases; sanitary engineering; legislation; demography; chemistry and pharmacology; and food and drinks. It also controls the following services: Sanitary inspection; the direction of venereal dispensaries; the institute of hygiene; the Hospital Morelos (maternity); the section of propaganda and hygienic education; the antirabic institute; and the school of health—a sufficiently comprehensive list of sections. As regards its actual work, a strong line has been taken with regard to vaccination. Authorised by a clause in the Federal constitution, the department "established a sanitary dictatorship in the State of Vera Cruz and sent down vaccination brigades" to carry out the law which now makes it compulsory on all. The central department has power to compel the enforcement in individual States of sanitary measures which are not provided for by the State laws, and is convening a congress of State sanitary authorities to consider the unification of the whole administration throughout the Federation. Besides small-pox, special measures were taken against cerebro-spinal fever, malaria, rabies, and bubonic plague, whilst it is recorded with satisfaction that the fight against yellow fever has resulted in its almost complete disappearance. The campaign against tuberculous and venereal disease is being actively carried on, and in both cases dispensaries for treatment are being established. It is of some importance to note that apparently in the future it will be necessary for those wishing to practise in Mexico to pass examination by the university there, but the conditions are not made clear. The main part of the Bulletin is taken up with the usual reports of the activities of the various departments and statistical returns. An unusual feature is a section devoted to sanitary progress abroad, and here the editors pay a high compliment to England by reprinting in full a translation of Sir George Newman's address on Public Education in Hygiene, with some short papers from France and the United States. The volume is well printed and produced. If succeeding volumes show similar results, Mexico will have no need to be ashamed of its Ministry of Health.

BEFORE AND AFTER THE PANEL CONFERENCE.

THE annual conference of local medical and panel committees, of which an account appears on p. 934, was held on Oct. 22nd in London. The impending shadow of the Royal Commission's report tended to cool the atmosphere of its deliberations, though here and there a speech recalled the warmth of a smaller meeting on the day before. A resolution of confidence in the Insurance Acts Committee as the one and only body qualified to represent the panel committees to the Government provoked a discussion from which it was learnt that all parties appreciated the value of unity in the profession, and this was reassuring. It would, indeed, be unfortunate if this unity were imperilled on minor differences of policy rather than of principle. The policy of the majority is at present noticeably cautious, and whatever may be the advantages of individual initiative there is no doubt that Unity is most easily wooed amongst the big battalions which she invariably patronises. It was abundantly clear that the value of personal liberty and the possible dangers of bureaucracy are acknowledged throughout the profession, and if that liberty should be definitely and deliberately challenged united action would doubtless take the place of the united inaction which the majority now desires. The relations of the insurance practitioner, the Ministry of Health, and the law, whilst they deeply interested the Panel Conference, did not, however, take up most of its time. Deficiencies or inaccuracies in the present machinery were suitably exposed, and the interesting question of collecting statistics was discussed at some length. It is admitted that the available information on panel and private practice, its costs, and their repayment, is at present deficient, and if a clearer case is to be presented for raising capitation fees and altering present conditions it is very desirable that accurate knowledge should be obtained. In answer to a proposed scheme it was suggested (to misquote J. M. Barrie), that the fault, dear Brutus, lay not in our staffs but in ourselves, and it is undoubtedly true that whatever organisation comes into being for collecting statistics must have the real personal coöperation of members of the profession if it is to accomplish anything useful.

THE SIZE OF THE THYMUS.

The real facts about the weight of the thymus have been fairly well known for some time, but the general opinion of morbid anatomists has been always a good deal coloured by their own experience. And it is in connexion with the thymus that the rarity of chances of carefully dissecting the normal human body soon after death has been particularly misleading—truly ignorance of the anatomy of the average people who walk about the streets is one of the main obstacles to the further progress of pathology especially along statistical lines. In the current number of the *Journal of Pathology and Bacteriology* will be found an analysis by Dr. A. B. Bratton of data which, collected in Prof. H. M. Turnbull's Institute at the London Hospital, probably form as satisfactory a mass of material as can be had. They comprise 337 persons up to 16 years of age who died from accidents, burns or scalds, asphyxia, under anæsthesia, or from the immediate results of these. In other words, the ordinary hospital population is excluded, for it is now realised that it is difficult for a child to get into a hospital and more difficult for it to reach the post-mortem room without suffering from something which causes wasting of the thymus. In line with this, Dr. Bratton shows that the thymus is larger and persists longer than is commonly supposed. It increases rapidly in weight during the first two years, then changes little till the seventh year, when it again increases to fall slightly after the eleventh year till the sixteenth. But more important are two other conclusions which emerge. In the first place, the weight of the normal thymus at any age is so variable that it is practically impossible to say in any individual case whether it is too large or too small. Thus the mean weight at 5 years is about 25 g. But the coefficient of variation of the weights of which this is the mean is about 35, so that a range from 16 to 34 g. will exclude about a third of the cases, and one cannot say that any one thymus is abnormally large unless it weighs fully 42 g. or too small unless it is less than 8 g. The second conclusion is that "we know of no gravimetric evidence that such a condition as 'status thymicus' exists." It seems time that some caution should be exercised in finding in a normal thymus a satisfactory cause of a healthy child's unexpected death.

THE LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

It was on August 1st, 1924, that the London School of Tropical Medicine became merged in the new London School of Hygiene and Tropical Medicine. At a meeting of the court of governors on Oct. 22nd some account was given of the present position and prospects of the school. The site for the new building is near the British Museum and has frontages on Keppel-street, Gower-street, and Malet-street. It was bought by the Ministry of Health in 1923 for £52,610, and it is hoped that on the plans of the architect, Mr. P. Morley Horder, the new home of the school will be ready for occupation in 1928. One cause of anxiety to the governors has been removed by the generous action of the trustees of the Rockefeller Foundation, who have amended their original undertaking, to provide a sum of $2,000,000 by promising to pay £460,830, which is the value in sterling of the money offered in 1922. By this the Rockefeller Foundation has cancelled the loss due to the gradual rise in the cost of sterling which threatened the school with a diminution in the value of the gift of more than £50,000 if conversion had been made at the rate of exchange now established. Concurrently with the task of preparing for the building, the Education Committee and the Director have given considerable thought to the general educational organisation, and the Board has recognised the necessity for taking early steps to secure the services of prospective heads of divisions in order particularly to have their advice and assistance before the details of accommodation in the new building and of its equipment are finally settled. A grant has been made by the University Grants Committee for this purpose, and in order to supplement in some essential respects the teaching for the Diploma in Public Health, which is now given at University College, Middlesex Hospital, and at the Royal Institute of Public Health. Arrangements will also be made for the equipment and organisation of the museum, which will play an important part in the educational work of the school. The Director, Dr. Andrew Balfour, has issued a report on the work of the Tropical Division for the year 1924–25. The number of students was 227, which was a record, and on the research side there have been important developments. A field station has been established in Southern Rhodesia, in pursuance of the view that available research funds should be applied primarily to setting up field stations, though expeditionary work may be undertaken in exceptional circumstances. Four research studentships in London have been arranged, and the general courses in tropical medicine and hygiene will in future be spread over 20 weeks instead of 13, and much more time will be given to clinical demonstrations and to the teaching of tropical hygiene. There is no doubt that this will equip students far more fully for their work abroad, and that the already excellent reputation of the school will be enhanced.

SHAKESPEARE AND MEDICINE.

On the occasion of the first social evening of the session of the Royal Society of Medicine a very large gathering of members and guests assembled at 1, Wimpole-street, W., to hear the President, Sir StClair Thomson, discourse on Shakespeare as a guide in the art and practice of medicine. Having introduced himself as a lecturer, in a neat and witty speech, the President referred to the remarkable knowledge displayed by Shakespeare of the history of medicine, to the references to the status of medicine in his own day, and to many startling clinical pictures scattered through his plays, and then proceeded to consider in how much the wisdom of the great dramatist could assist the doctor as a guide in the practice of his art, for "If our virtues did not go forth of us, 'twere all alike as if we had them not." From a large and brilliantly compiled selection of quotations we may select a few, seriatim, which any modern doctor might study with profit. No finer panegyric of the medical profession could be written than that put in the mouth of Cerimon :—

> By turning o'er authorities, I have
> (Together with my practice) made familiar
> To me and to my aid, the blest infusions
> That dwell in vegetives, in metals, stones ;
> And can speak of the disturbances that Nature
> Works, and of her cures ; which doth give me
> A more content in course of true delight
> Than to be thirsty after tottering honour,
> Or tie my treasure up in silken bags,
> To please the fool and death. *Pericles*, iii., 2.

It is to be noticed that Shakespeare, in these lines, recognises even in those Elizabethan days of superstition and wholesale drug-taking the vis medicatrix naturæ and gives the quite modern idea of curing our patients—

> With good advice and little medicine.
> *Henry IV.*, Part 2, iii., 1.

A justification for "case-books" is found in the wise note-taking of the Scottish doctor who attended Lady Macbeth: "I will set down what comes from her to satisfy my remembrance the more strongly." (*Macbeth*, v., 1.) The doctor must remember his patients are sick folk, and cannot judge their mental condition as he would that of healthy men and women. King Lear excuses the behaviour of his son-in-law by attributing much of his conduct to physical conditions:—

> No, but not yet;—may be, he is not well:
> Infirmity doth still neglect all office,
> Whereto our health is bound; we are not ourselves,
> When nature, being oppress'd, commands the mind
> To suffer with the body: I'll forbear;
> And am fallen out with my more headier will,
> To take the indispos'd and sickly fit
> For the sound man.
> *King Lear*, ii., 4.

Three centuries before the medical profession had adopted open-air treatment, Shakespeare had advised:

> The most wholesome physic of thy health-giving air.
> *Love's Labour Lost*, i., 1.

and recommended it as one of nature's best restoratives:—

> I pray you give her air,
> Gentlemen,
> This queen will live; nature awakes; a warmth
> Breathes out of her.
> *Pericles*, iii., 2.

> His highness yet doth speak; and holds belief,
> That, being brought into the open air,
> It would allay the burning quality
> Of that fell poison which assaileth him;
> Let him be brought into the orchard here.
> *King John*, v., 7.

Then, on being carried into the orchard of Swinstead Abbey, King John's first exclamation is:—

> "Ay, marry, now my soul has elbow room."

When considering therapeutic measures, said Sir StClair Thomson, we not uncommonly meet with a case which only requires the following pleasant prescription:—

> For so your doctors hold it very meet,
> Seeing too much sadness hath congeal'd your blood,
> And melancholy is the nurse of frenzy;
> Therefore they thought it good you hear a play
> And frame your mind to mirth and merriment,
> Which bars a thousand harms and lengthens life.
> *The Taming of the Shrew*, Induction, Sc. 2.

The advantages of what we would now call the simple life are shown:—

> Come; our stomachs
> Will make what's homely, savoury; weariness
> Can snore upon the flint, when rusty sloth
> Finds the down pillow hard.
> *Cymbeline*, iii., 6.

Encouragement is found in Iago's words:—

> How poor are they that have not patience!
> What wound did ever heal but by degrees?
> *Othello*, ii., 3.

and a patient's self-resistance may be raised by reminding him that:—

> Our remedies oft in ourselves do lie,
> Which we ascribe to heaven.
> *All's Well that Ends Well*, i., 1.

These are but a very few of the wise saws, having countless modern instances, which the lecturer quoted to show why Shakespeare was, and always must be, one of the greatest masters of medicine, in his astonishing acuteness of observation and his sensitive regard for "life's fitful fever." "Shakespeare's plays," he concluded, "will be read by physicians with profit to their patients when most of our modern medical text-books will be lying on the dust-heaps of literature."

Members and guests had the opportunity of inspecting in the course of the evening a most valuable exhibition of objects of Shakespearian interest, prepared by Mr. C. J. S. Thompson, M.B.E., Curator of the Wellcome Museum of Medical History. The collection included portraits of physicians and surgeons who lived in the days of Shakespeare, various portraits of Shakespeare himself, and specimens of plants, herbs, and roots mentioned by Shakespeare in his plays.

THE Chair of Midwifery and Gynæcology in University College, Dublin (National University of Ireland), rendered vacant by the death of Dr. Alfred J. Smith, has been filled by the appointment of Dr. Robert P. Farnan, who was at one time extern assistant to the Rotunda Hospital, and has been for many years gynæcologist to the Mater Misericordiæ Hospital.

Dr. J. H. Burn has been appointed to direct the Central Pharmaceutical Laboratory. It was announced by Mr. F. Pilkington Sargeant in his presidential address last May that the Council of the Pharmaceutical Society of Great Britain had decided to establish a laboratory for the standardisation of substances subject to the provisions of the Therapeutic Substances Act. The Director of the laboratory will have adequate qualified assistance and the help of an advisory committee on which Sir Nestor Tirard, Dr. H. H. Dale, and Sir Humphry Rolleston are serving as representing respectively the General Medical Council, the Medical Research Council, and the British Medical Association. Dr. Burn's distinguished academic record and work as pharmacologist and biochemist at the National Institute for Medical Research will fit him for a post which is likely to become of no little importance. The examination and standardisation of therapeutic substances is one of the really urgent questions of present-day medicine.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CLXV.—THE TREATMENT OF INFANTILE PARALYSIS.

THREE separate and distinct phases are presented by the average case of infantile paralysis and each phase has its particular treatment.

(1) *The Onset.*

There is usually a febrile period accompanied by great lassitude, headache, sickness, and flaccidity of muscles. In severe cases delirium and convulsions may precede a fatal issue. In others there may be absence of fever, and a child, at night apparently normal, may in the morning exhibit weakness of one or more limbs. There is no definite relation between the amount of initial constitutional disturbance and the degree of paralysis which ensues. Hyperæsthesia is almost a constant feature, with great tenderness of skin and muscles. Trophic changes are present early and the affected limbs become cold and reddish-blue in colour. Complete rest and warmth are the two most important essentials during this time. Support must be provided for the limbs, the joints being placed in the "normal" positions—hips and knees extended, ankles at a right angle. In upper limb paralysis the arm should be abducted at the shoulder, elbow at a right angle, and wrist dorsiflexed. The best means of securing such rest and warmth is by the provision of a plaster "shell." The body being first enclosed in cotton-wool, the plaster is then applied with the limbs, head, and back supported in the correct positions. If it is not possible to provide such a shell, a spinal frame with head-piece of the usual type, with the addition of foot or arm splints, makes a good substitute, but requires more attention. At this time no massage or electrical stimulation should be given and everything done to promote quietness and complete absence of mental or physical irritation.

(2) *The Recovery Period.*

This commences after a few weeks. The mental condition improves, irritability is lost, and the child becomes more interested in what is going on around it. Physio-therapeutic measures should now be instituted, commencing with the gentlest form of massage, "effleurage" or stroking movements. The benefit of massage is soon shown by diminution in the degree of coldness and cyanosis. After each massage treatment the joints of the limbs affected should be gently moved through their normal range and every possible active movement encouraged. During the period of muscle-training active movements should be performed against the least possible loads. As an example of this may be given the movement of extension of the knee produced by the quadriceps extensor. In case of weakness of this muscle the patient should not be asked to extend the knee in the ordinary sitting position with the weight of the leg and foot against the muscle, but the patient should be lying down with the affected limb on its side supported on a smooth table. In this way the effort needed to extend the knee is very greatly reduced. At this time electrical stimulation may be introduced. Its greatest use is in the production of muscular contraction in the paralysed muscles where a voluntary contraction is impossible. The muscle is thus exercised and prevented from rapidly degenerating into mere fibrous tissue. If a contraction cannot be obtained by a moderate faradic current it will be necessary to use galvanism. Later it may be found that faradism will produce contraction and it should then be substituted. About the same time it is often found that voluntary contraction begins to be possible. By this date the acute stage is well over and the paralysis is beginning to define itself. It may be found, for example, that the right leg alone shows paralysis and that the foot is cold with no power of dorsiflexion, a little power in the calf, no extensor power at the knee, but fair power in the hamstrings. Moderate power is present in all hip movements. Such a limb should be exercised well, bearing in mind that support must always be provided for the weak muscles. The child should wear, at night, a splint to keep the knee extended and the ankle at a right angle. In the application of a splint to maintain the right angle at the ankle it is of the utmost importance that the medical attendant should see that the nurse, masseuse, or mother who is responsible for the putting on of the splint should appreciate the fact that the heel must come down to the foot-piece. One so often sees such a splint applied with the heel a couple of inches away and the forepart of the foot alone meeting the foot-piece. In this way many cases of paralytic equinus are produced. In the daytime a walking appliance should be provided, and, in the case of such a paralysis as we have assumed, a "walking calliper" will be most suitable with a spring added to dorsiflex the ankle. With such an appliance a child will soon get about and will exercise the limb to the fullest possible extent. Should both legs be paralysed two callipers will be needed and in this case a walking machine is of great assistance. After a period of such treatment for 12 months the degree of residual paralysis may be determined.

(3) *Residual Paralysis.*

This is the stage in which little or no further change takes place in the recovery of power and in which surgery must attempt to diminish, as far as possible, the need for appliances and to utilise the residual power to its best advantage. The handicap of steels, leathers, and straps, loaded on a limb already severely enfeebled, must be reduced to its absolute minimum.

Much may be done, and the measures which offer the greatest chance of improvement are: (*a*) tendon transplantation; (*b*) tenodesis, or tendon fixation; (*c*) arthrodesis, or stabilisation of joints. These procedures, which have been largely developed during the past ten years, have proved their worth and are now a well-established part of the surgical repertory. Three simple cases may be taken to illustrate the utility of the three operations.

Paralytic Talipes Valgus.—Here the residual paralysis affects the tibialis anticus and posticus, and the foot is drawn over into a valgus position by the unopposed peronei. In this case the peroneus brevis, and sometimes the tertius as well, is transferred to the inner side of the foot and fixed to the insertion of tibialis anticus and scaphoid bone. In all such operations the transplanted tendon must run in as straight a line as possible from origin to new insertion so as to act at the best mechanical advantage. The foot, after operation, is supported in inversion, preferably by plaster, for six weeks, and at the end of this period the transplant must be "re-educated" and developed to perform its new function. Such a transplant when successful will overcome the valgus and so avoid the need for an outside iron and T-strap.

Drop-foot.—In this hypothetical case the dorsiflexors of the ankle are paralysed and an iron with a "stop" at the ankle-joint or an uplifting toe-spring must be worn so that the toes may clear the ground in walking. The paralysed tibialis anticus is exposed in the lower third of the leg and its tendon is cut across at its upper limit. A tunnel is bored transversely through the crest of the tibia and the cut tendon is looped through the bone and sewn back to itself and to periosteum with the ankle at a little less than a right angle. There is always some "give" after such a tendon fixation, so that it is advised to give the ankle about ten degrees more dorsiflexion than is desired in the ultimate result.

Unstable Ankle.—In such a foot the remaining power is so small that, when weight is placed on it, the ankle "wobbles" to one side or the other and is forced over into a deformed position. There may be some available muscle power, probably in peronei or calf. The precise distribution varies greatly, but the need for stabilisation of such a foot is apparent. The ankle-joint movement, plus the mid-tarsal movement, permits a range about the ankle as great as a ball-and-socket joint would, and it must be our object to remove the mid-tarsal movement and leave only the up and down hinge movement of the ankle-joint proper. There is, of course, a little side-to-side and rotatory movement at the ankle-joint, but it is slight, and amounts to very little when the mid-tarsal "wobble" is removed. Several methods of dealing with the mid-tarsal and astragalo-calcaneal joints have been devised, but the object in each case is the removal of the articular cartilage of the astragalo-scaphoid, astragalo-calcaneal, and calcaneo-cuboid joints and the procuring of bony union in these situations. Three months' fixation in plaster is required after such an operation. In a successful case it is then found that the foot is stable and can bear weight without rocking over. Usually a combination of the measures above mentioned is necessary, stabilisation of the mid-tarsus with the addition of a tendon transplant or tendon fixation being the common procedure. Mid-tarsal arthrodesis should not be attempted before the age of 8 years because of the amount of bone surface needed to ensure firm ankylosis.

Another common site for the use of arthrodesis is at the shoulder-joint, where power of abduction is lost and the arm cannot be carried away from the side, but where the shoulder can be effectively "shrugged" by the scapular rotators and elevators. In these patients it is usual to find a good forearm and hand. The articular cartilage of glenoid and head of humerus is removed and the arm fixed at a little less than a right angle from the side and 30 degrees in front of the transverse axis of the pectoral girdle. The shoulder is fixed in plaster in this position from the time of operation for three months and, after firm ankylosis is procured, the arm can be lifted from the side by the scapular muscles quite strongly, so that very much more use can be made of the non-paralysed forearm and hand. Because of the ossification of the humerus and glenoid it is not wise to undertake this arthrodesis until the age of 14 years.

Children's Hospital.

Special Articles.

THE PANEL CONFERENCE:

PROFESSIONAL UNITY AND DISCIPLINE.

THE annual conference of representatives of local medical and panel committees met at the British Medical Association's house in Tavistock-square, London, on Oct. 22nd, under the chairmanship of Dr. E. K. Le Fleming, of Dorset. This was the first meeting of the panel conference in the Great Hall, and the Chairman's opening words of congratulation to the British Medical Association on its new premises were cordially endorsed by the delegates.

Report of Insurance Acts Committee.

On the motion to receive the report of the Insurance Acts Committee (hereafter called the I.A.C.) for 1924–25, Dr. H. G. Dain, the chairman of that body, said that the conference agenda raised few big controversial questions because a special conference earlier in the year had dealt with the evidence placed before the Royal Commission, and because plans of development and improvement must wait on the report of that Commission. He drew attention to the new arrangements for ophthalmic benefit,[1] which were experimental and were the first attempt to add a specialist service to the general practitioner service. It was hoped that other similar services might be added. A new standard had been set up and the approved societies would have to be weaned from their previous arrangements. As yet a very small number of insured persons came under the scope of the scheme, and it had also been difficult to ensure that the right ophthalmic specialists appeared on the lists. The other important matter in the report referred to the disciplinary powers of the Ministry of Health. A deputation of the I.A.C. had put before the Minister four guiding principles[2] which had been proposed to the Royal Commission, and the Minister had agreed that these principles were sound, though they might not be easy to apply. There was no evidence as yet whether the interview had borne fruit, but it was noteworthy that there had been no decisions by the Ministry since the interview on June 18th, 1925, which were not in keeping with the principles suggested. That for which they had stood most firmly was that under no circumstances was an officer of the Ministry competent to set up a standard of treatment. Insured persons were entitled to the best services the duly qualified practitioner could give them, but a lay Ministry ought not to insist on a standard of treatment different from that which the doctor offered to a private patient.

Unity in the Profession.

Dr. E. R. Fothergill then moved a special resolution of confidence in the Insurance Acts Committee of the British Medical Association as the one and only body authorised to defend the honour and interests of insurance practitioners and to voice their wishes. The resolution urged all constituent committees loyally to support that Committee only, and to dissociate themselves from any action taken within the profession by others, which could only result in disunion and in rendering collective bargaining impossible. He had put down the resolution that morning on reading in the lay press an account of a conference held on the previous day which had appointed delegates to put its views before the Minister. He recalled the efficient action of the I.A.C. on various occasions; it represented 99 per cent. of insurance practitioners; it was recognised by the Government as expressing the profession's opinion, and it was a body which considered the good of the public as well as of its constituents. If panel committees coquetted with other organisations the public would think that the profession was in revolt. The future was likely to be far from calm and unity was essential.

Dr. Peter Macdonald feared that the proceedings referred to might lead the profession to suppose that the I.A.C. had done nothing, and this entirely wrong impression must be corrected.

Dr. Gordon Ward said that the Medical Practitioners' Union was in existence and was increasing in membership; it claimed no more support than it received. He believed in unity, too, and considered it very unwise to force the M.P.U. into antagonism.

Dr. E. A. Gregg said that the M.P.U. had never received the thanks that its work deserved. Though the I.A.C. seemed satisfied with the Minister's utterances the profession was not thus satisfied. It was their duty to press for the widest possible freedom for the practitioner.

Dr. H. B. Brackenbury thought that, although individual members of the profession could do what they liked, there must be no division of loyalties amongst panel committees. To send a separate deputation to the Ministry was a fatal step. Dr. Fothergill's motion was carried.

Disciplinary Machinery.

In support of a motion by Croydon that all complaints against insurance practitioners should be dealt with in the first instance by insurance committees, it was stated that the Ministry had deducted fines from doctors for failing to send in reports of their patients to tuberculosis officers, and that this had been done without reference to the insurance committee.

Dr. H. G. Dain said that tuberculosis officers reported such defaults to their regional medical officer who reported direct to the Ministry. The Ministry's view was that where no fact was in dispute it was unnecessary to refer to the insurance committee, and in the opinion of the I.A.C. it would be unwise to press against this view. Croydon considered the matter to be one of principle rather than convenience, but the conference did not agree, and the motion was lost.

Right of Appeal from Minister's Decision.

A long discussion followed a motion by Cheshire that insurance practitioners should have a right of appeal from the decisions of the Minister to the High Court, or, when removal from the panel was in question, to a medical tribunal if such were created. This appeal was to be exercised not only on grounds of procedure, but on the merits of the case.

Dr. L. J. Picton said that opponents had objected that litigation would be endless if such a right of appeal were granted; that the idea was unconstitutional; and that to ask for such rights suggested lack of confidence in the Minister, who could interpret the special terms of service of insurance practice which might not be understood by the common courts. But the practitioner had no fear of the common law, and it was regrettable that he was deprived of the right which every citizen enjoyed. This safety-valve had been shut down for fear of excessive litigation, and it had been a great mistake. They did not want to appeal against penalties, but in the rare event of an appeal to the High Courts being demanded they wanted the cases tried again de novo.

---

[1] Vide THE LANCET, Oct. 17th, p. 823.

[2] The four principles referred to are these: 1. That when a complaint has been dealt with by the bodies set up by the regulations for this purpose there should not be a liability to have the whole matter reopened by separate departmental action, either by the Ministry itself or by those bodies at the instigation of the Ministry. 2. That when a complaint has been made in one prescribed form penalties should not be inflicted in respect of offences not formally alleged or of offences which, if alleged, should have been formulated in a different prescribed way and might have required a different line of defence. 3. That full consideration should be paid to the findings or recommendations of a committee (whether Medical Service Subcommittee or Inquiry Committee) which has itself investigated the details of the case in mitigation of the heinousness of the misconduct even when proved. 4. That it is essential to draw a strict distinction between professional conduct in the attention given to a patient and the nature of the exact professional treatment given to the patient, and that the propriety or otherwise of any particular method or line of treatment should not be made the subject of investigation in connexion with the insurance service.

Dr. D. F. Todd moved an amendment to the effect that the appeal should be made to an independent authority only if the panel committee approved; but the Conference thought that this gave unsatisfactory authority to the committee, and the amendment was lost.

Dr. G. C. Garratt said that the present machinery had broken down; the Ministry's powers were a standing menace to the profession and it could only have gained them by a lamentable oversight. They were more fundamentally foreign to the British Constitution than any other legislation since Stuart times.

Dr. Brackenbury remarked that the I.A.C. had suggested to the Royal Commission that all personal disputes as to judgment, neglect, and the like, should be taken out of the insurance machinery and should be treated exactly as in ordinary practice. It had also suggested that there were only three possible grounds for complaint—namely, giving a false certificate, taking money from a patient after giving an undertaking not to do so, and habit or conduct such as ought to remove a man from the panel.

The Conference decided that for the time being it had been sufficient to ventilate its opinion, pending the Royal Commission's report, and accordingly passed on to the next business.

Administrative Items.

A motion that when a practitioner recommends an approved society to send a member to an ophthalmic surgeon whose name appears on the list he should have the right of nominating the surgeon was amended so that "suggesting" took the place of "nominating." It was pointed out that suggestion was always possible and that the motion had lost point, but the Conference passed it nevertheless as a record of its opinion. The proposal was made that a distinction should be made on the lists between operating ophthalmic surgeons and practitioners whose experience enabled them to do refraction work, but this was not approved. The Conference agreed to a motion by the I.A.C. that a return should be made to the earlier practice of intimating to patients, on the notices sent to them on the death or retirement of their doctor, that unless they made a fresh choice within 14 days they would be transferred to the successor's list.

The question of the abuse of such a rule by rapid re-transference of practices thus transferred was passed on to the I.A.C. for consideration. A resolution against unnecessary records of attendances, which tend to obscure the important clinical notes, was carried with little or no opposition, and a proposal by Lincoln that doctors should have permission to issue intermediate convalescent certificates before 28 days' treatment had been given also received assent. It was agreed that the time of issue should be left to the doctor's discretion and that the maximum period covered should be one month.

Dispensing Allowances.

Essex moved, and the Conference agreed:

> "That, in view of the difference between the average cost of drugs dispensed by a chemist in the area of the Essex Insurance Committee, which amounts to 8·7*d.* per insured person per quarter for the year 1924, compared with the amount of the capitation fee paid to rural practitioners for the purpose of dispensing drugs—namely, 6*d.* per quarter per insured person, the Insurance Acts Committee be asked to take such steps as they may deem necessary to obtain an increase in the remuneration paid to rural practitioners who undertake their own dispensing."

Evidence of an inquiry into the costs of prescribing and dispensing was given by Northumberland, and Dr. J. P. Williams-Freeman said that the rural subcommittee would like to have such evidence from other areas. Fees for serum dispensing were also discussed and referred to the I.A.C., and the Medico-Political Committee was asked to consider further the standardisation of methylated spirit.

Treatment of Seamen: Private Patients.

Essex drew attention to the practice of the Seamen's National Insurance Society in urging its members to go to doctors whom it recommends. The low rates accepted by practitioners who work for this society were also considered.

Dr. Alfred Cox said that the question was an old one, and the B.M.A. Medico-Political Committee was trying to get the society to raise the scale. The recommendation of certain doctors was intended to benefit the seamen themselves, for these doctors were experienced in dealing with them and the seamen preferred their advice. It was, said Dr. Cox, very difficult to induce members not to accept the lowered fees, but Southampton had taken a lead against this practice.

Dr. J. S. Manson, in moving a resolution for Warrington, said that it was not clear what was the position of an insurance practitioner if an insured person not on his list wanted to come to him as a private patient. It was suggested by other speakers that if the patient persisted in his wish to be treated privately after it had been explained that he could be treated under the Act there seemed to be no reason why he should not be a private patient; but that it was important to have his assurance in writing.

Collection of Statistics.

Kent introduced a motion deploring the inability of the profession to produce authoritative statistics on such matters as fees, mileage, costs of transport, and the average income of medical men, and suggesting an organised campaign to collect such statistics, for which a part of the National Defence Trust's funds might be utilised. In a preliminary statement, Dr. A. Cox said that 270 practitioners were already making returns of their insured and uninsured patients, and that 150 model account books had been forwarded, of which 20 had so far been filled up and sent back. He thought that the scope of this investigation was big enough if only the doctors would return the figures; it was individual work rather than theoretical plans that were needed.

Dr. Gordon Ward (Kent) said that the country should be mapped out into districts; every practitioner in a district should be personally encouraged by travelling investigators to give the necessary particulars, as the people willing to send in figures by themselves were a special group and not representative. Figures of income in the so-called comparable professions should be collected. The isolated instance was of little value, but the general district survey was invincible as evidence. A central statistical committee should be set up, and, although a minimum of £5000 would be required for the purpose from the National Fund (which stood at £78,000), the evidence that would be collected might eventually mean a difference of 6*d.* in the capitation fee of 15 million insured persons.

Dr. J. W. Bone did not think £5000 would go far.

Dr. Williams-Freeman thought that a permanent statistical committee of the B.M.A. would be very useful. The Conference eventually agreed with Kent that information was desirable, and referred the matter to the I.A.C., without, however, instruction as to the exact methods to be adopted.

Other Problems.

A suggestion that a limit should now be fixed to the National Defence Fund was also referred to the I.A.C. and there was considerable discussion of the failure of many local committees to subscribe. Coöperative action between practitioners and regional medical officers was also considered, and the possibility of redress when unfounded charges were made by approved societies.

The Conference expressed its opinion that insured persons who are no longer entitled to benefit should be notified of the fact by the approved societies.

The Chairman, Dr. Le Fleming, was unanimously re-elected for the ensuing year. The Conference concluded at about 6.45 P.M.

PANEL CONFERENCE DINNER.

A dinner to the Insurance Acts Committee was held at the Trocadero Restaurant, London, in the evening, at which, as in previous years, Dr. H. J. Cardale, chairman of the London County Panel Committee, occupied the chair. A large number of delegates to the Panel Conference attended and derived entertainment from many witty speeches, from the slightly miraculous efforts of Mr. Herbert Collings and from the songs of Miss Ethel Kemish. Proposing the health of the members and officers of the Insurance Acts Committee, Dr. J. O. Summerhayes said that what was wanted on that Committee was "a strong mixture," and they had got it. The Committee was leading them—though he hardly knew where; in spite of the rivalry of another organisation it would continue to do so, and as long as it made arrangements by which the man who did his duty by his patients was not defrauded of his proper recompense, then he, for one, would be content. Dr. H. G. Dain replied amusingly for the I.A.C.; Dr. Alfred Cox deplored the fact that no doctor ever reads anything, and Dr. G. C. Anderson discussed Dr. Cox's approaching departure for South Africa. Dr. R. A. Bolam proposed the health of the medical Members of Parliament and Dr. Haden Guest, M.P., replied. He said that the medical committee of the House, which had 14 Members, put the medical interests of the community before the particular interests of parties. He considered that medicine was a particularly valuable training for public life; what was needed in politics was a more scientific attitude, and the successful doctor was wanted there far more than the successful financier or grocer. Dr. Graham Little, M.P., also spoke of the Parliamentary Medical Committee, of which he is secretary. There were ten times as many lawyers as doctors in the House, and the balance should be redressed. It was unnecessary and even undesirable to give up practice on entering political life. Sir Richard Luce, M.P., largely endorsed the views of his colleagues and described his own unexpected political debut. The dinner ended with "Auld Lang Syne."

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

James Mackenzie Institute for Clinical Research, St. Andrews.

ON Oct. 20th Prof. Adam Patrick described some observations on temperature and pulse-rate, showing an interesting series of charts illustrative of most of the common fevers. He strongly advocated greater accuracy in recording temperature, drawing attention to the common practice of nurses in omitting to record temperatures below 97° F. Similar inaccuracy was common in regard to high pulse-rates. The physician, wherever possible, should check the records by his own observations. He insisted on the extreme value of graphic records of the pulse-rate, a gradual rise in rate being more readily detected where this method is employed. In rheumatic fever, for example, a pulse chart was the best indicator of the onset of endocarditis. He deprecated the use of the word "normal" in relation to a fixed point of temperature such as 98·4° F. This might be regarded as the upper limit of normal temperature, but in nearly all healthy individuals the average morning temperature was considerably lower. As a rule the pulse-rate increased about ten beats as the temperature rose one degree, but there were wide differences in this ratio in different diseases. He drew attention to the fact that in many febrile conditions the quickened pulse of fever was succeeded during convalescence by an unusually slow rate. He considered that all these matters required more accurate recording and fuller investigation.

Prof. Harvey Cushing's Address.

On Oct. 23rd Prof. Harvey Cushing delighted a large audience with an informal talk, illustrated by references to his own special subjects of study, on the comparison between research work as carried on in hospital and in general practice. He pointed out that the necessary stimulus for research was the same—namely, the common desire to find satisfactory answers to problems of difficulty which present themselves for solution. The worker who saw all his patients in an institution (as he did in America) had better opportunities for obtaining records of his special cases and more time and facilities for investigation than the general practitioner. He himself was directly descended from three generations of general practitioners, who had practised in the same district, and one of his most cherished possessions was a collection of the case-books of these ancestors. Not only were they records of illness in individuals, but they provided, by their continuity, material for the study of familial tendencies which could be obtained in no other way. They demonstrated the extreme value of accurate and continuous records in medicine. To enhance the value of records, he advocated the employment, wherever possible, of instruments of precision; though it must be clearly understood that these must never overbalance the general judgment of a case. He referred to the ophthalmoscope, the sphygmomanometer, the polygraph, the electrocardiograph, and the thermometer, pleading for more accurate use of the latter (as did Prof. Patrick in his address). Routine daily records of facts such as temperature might often appear to be a waste of time, but not infrequently an observation of the greatest importance would crop up.

In connexion with his special study he warned practitioners that, in cases of cerebral tumour, any of the cardinal symptoms (headache, vomiting, choked disc) might be absent, and, indeed, that cerebral tumours of slow growth might attain considerable size with no symptoms whatever. In his experience the intracranial cavity was the commonest site of tumour growth in the body. He spoke of the importance of detailed recording of such a symptom as headache (site, time of occurrence, and character) on Mackenzie's lines. If any symptom was carefully studied in this way important leads were sure to emerge. He commented upon our ignorance of the mechanism of production of headache. In conscious patients direct manipulation of the cerebral substance produced no sensation, but acute pain was experienced if the membranes were pulled upon, or an artery clipped or ligatured. Clinical research, whether by specialists or by general practitioners, was carried out by similar means and with the same object. The inquiring mind, that would not rest till it got an explanation, was what mattered.

Edinburgh: Royal Medical Society.

At the opening of the 189th session of the Society, Sir James Purves-Stewart delivered the inaugural address on comradeship in science. The Senior President, Dr. Drummond Shiels, M.P., was in the chair. Sir James Purves-Stewart, said his subject was selected mainly to address to those of his hearers who would seek their fortunes elsewhere than in Edinburgh. The capacity of combination with one's fellows and the faculty of profiting by such combination was a fundamentally biological principle. The lowest type of herd, said the speaker—quoting examples in the animal kingdom—was that of the communists, where all were equal. There was then the type which had developed specialised classes, consisting perhaps of workers and fighters. And, lastly, there was the type which had a kind of monarchy, where one individual was higher than all the rest—such as in the case of the queen bee. Man could only reach his highest development by following this instinct, with its pride of family, profession, country, or race. Every ordinary individual desired to be one of a crowd. In civilised communities the herd instinct dominated. If the herd instinct was lost in a man he became selfish and vicious. Passing on to discuss the beneficent effects of gregariousness, coöperation, or comradeship in professions, such as the medical profession, Sir James Purves-Stewart said it would be inappropriate at such a time to discuss abstract socialism as a political mode of life. But socialism of a constructive type had been going on in a small but important part of the community. Men of science had pooled their knowledge for the general advancement of science, and more, they let the whole world profit. The working man rode every day for twopence in an electric train. He knew nothing of electricity, and perhaps would never be able to master the application of such knowledge to the problem of his transport. He reached his destination; he was taken to the surface again by a moving staircase, of the mechanism of which he was again entirely ignorant. And if he stepped off with the wrong foot first and was seriously hurt he would be taken to hospital, where medical science, of which he knew nothing, would do all that science could do for him, and would do it for nothing. That was the socialism of science. What did it receive in return from those who profited by it? They all knew the answer. Our hospitals were chronically in debt; research was half-starved. Compared with the manufacturer, the merchant, or the financier, very few scientists were wealthy men. In fact, practically no return was made by the great body of laymen in any way commensurate with the advantages which they so eagerly accepted.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Hygiene and Budgets in Paris.

SCARCITY in the public funds at Paris is noticeable in two striking ways. The onset of winter brings discomfort from cold in apartments, office buildings, laboratories, class-rooms, and assembly halls of all sorts, and the large libraries are greatly hampered by insufficient illumination. The medical profession is thus considerably affected. The Academy of Medicine, whose pre-war budget sometimes rose to 65,000 francs in days antedating later huge advances in general costs, has been so poorly warmed during this autumn that a committee of the academicians has been obliged to wait upon the public powers with a request for adequate fuel. A Paris newspaper observes that, since charity and lotteries are scarcely applicable here, the savants of the Academy will have to remain at home.

Closed Pharmacies.

The closure of pharmacies at night, on Sundays, and on holidays constitutes one of the few drawbacks of our capital. All-night service is available at one pharmacy on the Boulevard de Montmartre, rather a long way from the Opéra, and a pharmacy near the Gare St. Lazare remains open until midnight. These two pharmacies appear to constitute the practical night service at Paris, unless one has recourse to the mairie of his arrondissement for official direction to a pharmacy supposedly open. Pharmacies closed at night, on Sundays, and on holidays usually post up a list of pharmacies, of which one should always be open. One often makes troublesome trips to these places only to find them closed after all. This system of closure is due to action by the pharmacists' union. A pharmacist preferring to keep open shop has recently tried it, with great benefit to the public and displeasure to his syndicate. This case has caused legal action and is not yet settled. Anyone who is ill at Paris had better do his pharmaceutical shopping early.

Surgery and Taxation.

Taxes will continue to hamper life generally in France for a long time to come, as they do everywhere. Imposts on anæsthetics and other drugs and medicinal substances complicate the surgical and medical situation not a little. The maisons de santé, or private hospitals, of Paris, now taxed on a hypothetical profit basis of 20 per cent., are so gravely menaced by this difficulty that surgery is by no means without danger of being relegated to makeshift operations in private houses, since the general raising of prices to cover the taxation is scarcely practicable for large medical and surgical needs. A committee of the French Surgical Syndicate, which has just been in session, is considering this matter.

Treatment of Congenital Syphilis.

The importance of treating syphilis preventively, by prompt attention to the pregnant mother and to infancy and early childhood, is now comprehended universally, and at the Paris conference on congenital syphilis, to which I referred in my letter last week, the following conclusions were adopted: Congenital syphilis should be treated promptly and during a number of years. Not only must symptoms be controlled, but real cure must be sought. Active signs require treatment by progressively increasing doses of arsenicals, contra-indications being duly observed. Fundamental treatment with mercury or bismuth should be instituted when clinical and serological signs have ceased or if the disease remains latent. Opotherapy should accompany antiluetic treatment if endocrine function be insufficient. Breast-feeding by the mother is imperatively demanded, and in no case may a wet-nurse be employed. Observation should continue for a long time after the cessation of treatment.

Music in Hospitals.

While music has been advocated for systematic application after anæsthesia and in other ways, it is also useful simply as a recreation, especially in institutions containing many incurable cases, and patients who must drag out a long, hopeless existence. A group of interested persons has just provided a fine gramophone for a large medical ward in the Hôpital Lariboisière. The instrument cannot well be installed in the general ward, since it could not always be acceptable to all the sick. It is being installed in a small room adjacent to the ward, and to this modest "salon" those of the patients who desire may resort for a little solace. The records selected supply a variety of music, but the best of the classics predominate. This thoughtful provision should aid materially in cheering the indigent and resourceless sick, although less ambitious than the plan to provide every hospital bed in London with a listening-in set.

NOTES FROM CANADA.

(BY AN OCCASIONAL CORRESPONDENT.)

Lord Dawson at McGill University.

Lord Dawson of Penn was given the honorary degree of Doctor of Law at the autumn convocation of McGill University, held on Oct. 6th. In an address delivered after receiving the degree Lord Dawson said that a university must not think only of future vocations when providing students with their equipment for life. The training of character, essentially a duty of a true university, would not be effected in an institution that was a mere emporium of facts. Adequate facilities were not in themselves sufficient, unless the student mind received training from the teaching system, and the brilliant and rapid advances that invention was making were apt to obscure the spirit of education. Lord Dawson accorded high praise to McGill as the first University in the Empire to send a fully-equipped hospital to France during the war; no hospital in the Service had surpassed it in reputation. He concluded an eloquent address by urging the students to play their full part in the affairs of the country and of the Empire. Sir Arthur Currie, the principal of the University, laid especial stress on the idea that their duty did not lie in application to study and to study alone; their duty was to realise and participate in the problems of Canada. He showed what McGill had meant in the life of Canada, in medicine and surgery, in commerce, in the schools and colleges, in peace and in war, and reminded them of the young men who had crowded their way to death 11 years ago at the call of their country. Those in the University to-day were born too late to answer that call, but still had their duty. Every great crisis in Canada was an Ypres, a Vimy, a Passchendaele, and a great battle for their country lay before them—a battle against ignorance and prejudice and wrong.

On Oct. 12th Lord Dawson gave an interesting address to the Academy of Medicine, Toronto, on High Blood Pressure. He discussed especially the influence of anxiety and strain.

Objections to Milk Pasteurisation.

The Union of Coöperative Milk Dealers of Montreal object to certain of the milk regulations about pasteurisation, and have asked the city council of Montreal to compel farmers providing milk for pasteurisation to pass the same strict examination and qualify to the same degree as those who furnish natural or raw milk, which is called special milk in the by-law. They base their conclusions on the premise that germs enter milk between the time it is drawn from the cows and pasteurised; if milk be not treated immediately after it is drawn it is useless to pasteurise it because the products of bacterial action are already present though the milk is apparently given a new lease of life. They question adversely a clause in the regulations demanding that milk from a herd in which a tuberculous or doubtful cow is found shall be pasteurised before it is sold, by which no milk may be sold as raw while the suspected cow remains in possession of the owner of the herd. It is pointed out that the enforcement of this regulation does not protect the public, and will allow unscrupulous dealers to circumvent the law and sell natural milk, although a cow in the herd may be tuberculous; the cow is simply transferred to another person for the time being in order to hoodwink the inspectors. They insist that pasteurisation is practically useless unless applied immediately after milk is drawn, and that the only way to guarantee pure milk is to ensure that it is clean and healthy in its origin. It must come from healthy cows which are able to pass a high test such as that required for raw milk.

Standardisation of Education in Canada.

Prof. Stephen Leacock, addressing the students of Queen's University on Oct. 16th on the Work of the Canadian Universities, drew attention to the danger of over-standardisation in education. He pointed out that there was a tendency nowadays, in America at any rate, to reduce everything to a standard or pattern. In the industrial world this was admirable; but though the standardisation of a Ford car was excellent the standardisation of brains was dangerous. It did not do to have every school and every college like every other school and college. There was in Canada a notable contrast between the American ideal of education and the British—or what was till yesterday the British. Prof. Leacock considered that in Great Britain the training of the student was on freer lines, less definite, less mechanical; it was not cut and divided into parts, and more play was left for individual variety, for individual preference, and for individual difference. Education, in short, he said, contained a large element that was more or less at random and spontaneous. He uttered a warning against the spreading tendency in Canada to adopt the American standardising type of education. Education, he said, needs freedom, variety, and elbow room.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are some of the health statistics of four seaport cities for 1924:—

Name of city.	Estimated mid-year population (R.-G.).	Birth-rate.	Death-rates per 1000 of the population.				Death-rates per 1000 births.		
			All causes.	Tuberculosis.	Cancer.	Resp. diseases with influenza.	Neonatal mortality.	Infant mortality.	Maternal mort. from childbirth.
Glasgow . . .	1,051,000	24·1	16·1	1·46	1·21	3·7	38	119	5·5
Bristol	386,200	18·7	12·8	1·16	1·34	2·8	34	72	4·6
Hull	296,800	22·4	13·5	1·32	1·23	3·4	32	87	3·6
Newcastle-upon-Tyne . .	285,900	22·2	13·5	1·47	1·25	3·0	45	100	2·4

Glasgow.

Dr. A. S. M. Macgregor (interim medical officer of health) submits the report for the year 1924, during which Dr. A. K. Chalmers was still medical officer of health for the city. The local estimate of the population exceeds that of the Registrar-General by 45,000, and if the local estimate be used the rates per 1000 of the population in the above table would be reduced by about 4 per cent. Thus the Registrar-General's death-rate of 16·1 would become 15·4.

In the maternity and child welfare scheme it was decided to experiment in the provision of home-helps, and in August about 30 to 40 suitable women were enrolled for the purpose, but their services were only sought on nine occasions. The number of women admitted to the antenatal wards of the Royal Maternity Hospital was 706, an increase of 100 when compared with the previous year. The number of new cases attending the antenatal clinics was about 3700, the births being 25,330. There were 592 cases of ophthalmia neonatorum notified. The symptoms of the disease appeared within 12 hours of birth in 46 cases, between 12 hours and 4 days in 221 cases, between 4 and 8 days in 206 cases, and later than 8 days in 119 cases. Of the total cases, 49 were classified as gonococcal, 348 as non-gonococcal, and 195 were unclassified. Of the survivors among the gonococcal cases, 3 had corneal scars in one eye without the sight being impaired, 1 had a corneal scar with impaired sight in one eye, 1 had corneal scars in both eyes with unimpaired sight, 1 had scars in both eyes with impaired sight, and 1 was blind in both eyes. Of the non-gonococcal cases none of the survivors had impaired sight. Owing to the difficulty frequently experienced by midwives in obtaining the services of a doctor in an emergency, an alteration of the rule of the Maternity Hospital, by which admission can only be obtained on the direct request of the medical attendant, has been made, and the Maternity Hospital will now admit such cases when a medical man is not available.

Two cases of small-pox were treated in hospital during the year, both being infected abroad. Infantile vaccination is fairly well maintained in Glasgow, about two-thirds of the infants in the city having been successfully vaccinated during the years 1920 to 1922. The number of conscientious objectors varies, however, in the different wards. Thus in Fairfield and Gowan 37 and 35 per cent. respectively of the infants were not vaccinated during 1924, while in Kelvinside the percentage of conscientious objectors was only five.

An unusually extensive school outbreak of scarlet fever was recorded just after the summer holidays, 45 scholars and 2 teachers being infected out of a total of 1030 scholars and a staff of 18. Encephalitis lethargica was more prevalent during 1924, the maximum being reached during the month of May. There were 391 cases with 46 deaths. At Ruchill Hospital serum immunisation against measles has been used to a limited extent. The incidence of the disease was thereby considerably reduced among susceptible contacts, and in a few cases the disease developed in a modified form. A considerable amount of hospital accommodation has always been found for badly housed cases of measles and whooping-cough in Glasgow, and during 1924 it was decided to appoint additional nurses to supervise home-treated cases of these diseases.

A report on the deep X ray treatment of tuberculosis by Dr. J. A. Wilson and Dr. Fergus Henderson shows that beneficial results were obtained in certain cases of chronic non-pulmonary tuberculosis. This treatment was especially satisfactory for cervical glands and for bones and joints when the lesions were single and superficially placed. For the deep joints, such as the hip, and in all joints where there was extensive exudation, the results were unsatisfactory.

Bristol.

Dr. D. S. Davies reports that with a view to the coördination of the medical services of the city the school medical officer has been appointed deputy medical officer of health, and that arrangements were made during 1924 whereby children found by the maternity and child welfare staff to be suffering from eye troubles or crippling diseases, such as rickets, infantile paralysis, &c., are referred to the school clinics for treatment. During the year 97 cases of eye trouble and 43 of crippling diseases were so referred. The health committee contemplate developing Frenchay Park Sanatorium into a complete orthopædic hospital in order to avoid the present inconvenience of sending cases to distant hospitals. Milk samples, to the number of 50, were examined for tubercle with two positive and one suspicious result. Visits to the farms were unsuccessful in finding out the offending cows. The hospital accommodation for infectious diseases has been reported as inadequate for several years, there being 240 beds for a population of 386,000, and in April the council decided to provide 56 additional beds at Ham Green Hospital. The work is now in hand.

During 1924 an inquiry was carried out by Dr. Dorothy Staley as to the sequelæ of encephalitis lethargica. The inquiry covered 76 patients, whose illness began during the years 1919–23. Of the 76 cases, 26 had completely recovered, 4 could not be traced, and 4 had died. Of the remainder, 6 were totally unable to work, 15 showed partial inability to work, and 17 suffered from apathy, dullness, drowsiness, and defective memory. Two were affected by dementia, 2 by viciousness, and 35 suffered from various forms of paresis. Many of the patients presented a multiplicity of nerve lesions, and a number were in a very grave condition. In few was there any appearance of improvement taking place at present. Dr. B. A. I. Peters, the R.M.O. of Ham Green Hospital, reports that during the three years from the adoption of the Schick test for the staff until the end of 1924, no immunised member of the staff has contracted diphtheria nor has anyone been incapacitated from duty owing to the inoculations. Previous to this, an average of five members of the staff was attacked annually by diphtheria, and in 1921 no less than 12 developed the disease.

Hull.

Dr. J. Wright Mason submits his forty-third and last report, and in doing so contrasts some of the statistics of the first and last years of his tenure of office. Thus when 1881 is compared with 1924 the population shows an increase from 155,160 to 296,800, the birth-rate has declined from 36 to 25·8, and the death-rate from 23 to 13·5. The rate from zymotic diseases was 6·12 in 1881 and 0·6 in 1924, whilst infant mortality has declined from 193 to 77.

Dr. Katherine Gamgee reports on the maternity and child welfare work. During 1924 150 cases of eye discharge in babies were investigated, of which 122 were classed as true ophthalmia neonatorum. In three of the 122 cases there was injury to the cornea, in one case there was blindness of one eye, and in one case blindness of both eyes. In the first quarter of the year the maternity home was transferred to Cottingham and was temporarily established in the new pavilion of the infectious diseases hospital. The available accommodation has thus been increased from 11 beds to 20. The sisters of the maternity home act as municipal midwives in turns, and an antenatal clinic is held at 14, Kingston-square for cases seeking admission to the maternity home, for all abnormal cases, and for primiparæ applying for a free midwife. Dr. Ethel Townend, the part-time medical officer to the maternity home, conducts the antenatal clinic, and between June and December, 1924, she saw 866 cases. Of this number, 87 were found to be abnormal and to require treatment. One case of severe heart disease was admitted to the home and treated for some time. Labour was induced prematurely and mother and child were discharged in a satisfactory condition. Of 34 cases of disproportion between the head and the pelvis labour was induced in 12 cases. Amongst the other antenatal patients were six cardiac cases, 12 external versions, seven cases of albuminuria, two of antepartum hæmorrhage, one of acute pyelitis, and eight cases of severe varicose veins. Dr. Gamgee conducts an antenatal clinic for cases sent by midwives or doctors. These cases numbered 160 during the year. A real start has therefore been made in preventive midwifery in Hull.

The notifications of encephalitis lethargica numbered 35 and eight deaths were recorded. Ten of these cases were admitted to hospital and several were found to be suffering from some other disease, and in three cases death ensued from other causes Hull has begun in earnest to tackle the conversion of privies and pail-closets to water-closets. The conversions effected during the last four years were 183, 594, 1598, and 5163. The number of privies at the end of 1924 was 10,000 and of pail-closets 22,000.

Newcastle-upon-Tyne.

Dr. H. Kerr reports that, in spite of industrial depression, unemployment, and a slight rise in the cost of living, as a whole the year has been exceptionally healthy. The hours of sunshine recorded at Armstrong College were 728 and at Cockle Park, a few miles north of Morpeth, 1313, showing what is lost by atmospheric pollution. There were 26 deaths from diabetes as compared with 38 in the previous year. The improvement may be due to the introduction of insulin, but, on the other hand, the deaths in 1922 and 1921 were only 28 and 29 respectively. Influenza was prevalent during January and February, and caused 71 deaths. Small-pox appeared in the city for the first time since 1910. There were five mild cases among persons unvaccinated or who were over 30 and had not been revaccinated since infancy. The number of infants vaccinated was 70 per cent. in 1923 and dropped to 61 per cent. in 1924. Of the 28 cases of typhoid fever notified, all except two were traced to the consumption of ice-cream at the coast. At the time of the occurrence there were no by-laws in force for controlling ice-cream manufacture at Tynemouth, and ice-cream was discovered to have been manufactured in a house in which a case of enteric fever had occurred. Eight of the Newcastle cases occurred in a single family of nine persons, of whom three died. These were the only deaths in the city from this disease. There were 96 notifications of encephalitis lethargica and 15 deaths. The type of the disease was more severe than in preceding years, and most of the cases occurred in the poorer and overcrowded quarters of the city. Only in three cases was there evidence of transmission of infection from one member of a family to another. It is considered probable that the mental impairment which resulted in 19 of the survivors will be permanent.

Dr. A. F. G. Spinks, in the maternity and child welfare report, states that antenatal work makes some progress. Thus 414 expectant mothers attended the six antenatal clinics. The births for the city numbered 6335. The "handy" woman has almost disappeared in Newcastle and all but six of the 43 practising midwives are trained women. The death-rate among illegitimate babies was less than among the legitimate, and it is pointed out that 174 of the 253 illegitimate babies were under the supervision of the centres.

Dr. Kerr points out that men affected by tuberculosis have little chance of obtaining a new house, and suggests that the health committee might subsidise persons of this class to enable them to obtain corporation houses. He emphasises the futility of benefiting the health of the consumptive in the sanatorium and then allowing him to return to appalling home conditions. The health committee is considering the establishment of a workshop where patients returning from the sanatorium could do work according to their limitations. The open-air school on the Pendower Housing Estate became an established fact during the year, but no adequate provision has yet been made by the health committee for surgical tuberculosis. The health committee purchases "Certified" and "Grade A (tuberculin-tested)" milk for the use of the City Hospital, and the agricultural department of Armstrong College is now conducting much local teaching on the farms of the northern counties, and is also organising clean milk competitions. The transport of milk remains unsatisfactory, but the L. and N.E. Railway are said to be considering the adoption of an improved type of milk wagon. The effort to secure the rinsing of empty milk cans before return is making progress. Thus in 1922 2·5 per cent. were found by the inspectors to be unrinsed, in 1923 0·5 per cent., and in 1924 0·2 per cent. The last figure is the result of the examination of 25,015 empty churns. Dr. Kerr has no improvement to report in housing conditions. Only 11 municipal houses were completed during the year, but some hundreds more were in course of construction at the close of the year. 268 houses were erected by private enterprise. "There is still no power," says Dr. Kerr, "to control the cases of heartless profiteering on the part of the exploiters of so-called furnished lodgings."

MENTAL HOSPITAL REPORTS

THE seventy-ninth annual report of the *Devon Mental Hospital* at Exminster is just what such a report should be. Over 1170 patients are accommodated under the charge of four medical officers, and every effort is made to keep the institution in the front rank. The visiting commissioner mentions the many improvements since his previous visit, which include better baths, more stringent precautions in the administration of medicines, and the provision of bed tables, pianos, and aluminium bedroom, kitchen, and table ware. The recovery-rate for the year was 32·29 per cent. and the death-rate 6·92 per cent., a satisfactory decrease on previous years and the lowest on record since 1899. Post-mortem examinations were held on 60 per cent. of the fatal cases. Twenty cases were discharged on trial with money allowances, and parole has been increasingly allowed. There has been a gratifying increase of private patients able to afford a moderate fee and sent in by doctors practising in the county. The sanatorium has been reopened for the isolation of infectious cases; the hospital has been troubled by small epidemics of dysentery and typhoid. The pathological laboratory has carried out the routine work satisfactorily. Blood cultures in the early days of doubtful fevers revealed seven cases of typhoid, which might possibly never have been recognised clinically. A systematic search for the source of the typhoid infection is now being conducted. A new operating theatre was opened in the course of the year, and the hospital has now a full staff of visiting specialists from Exeter, who visit monthly. The dental surgeon, in addition to his routine work of extractions and fillings, examines all new patients on admission. An X ray department will be in full working order shortly. Every effort is made to bring variety and interest into the lives of the patients. No less than 360 went for all-day motor charabanc picnics during the summer, while many others went out for half-day excursions gathering fruit and flowers. During the winter weekly dances and concerts are held, and a Pathé cinematograph and a wireless set have been installed. The patients much appreciate the new ward socials, which allow them to stay up till 9.30 P.M. Fêtes, sports, and games are also included in the programme. The occupational therapy includes printing, weaving, mat-, net-, stocking-, and shoe-making. Patients who wish to wear their own clothes are allowed to do so, and the workhouse type of garment is being done away with as it becomes worn out. Thirty attendants and nurses hold the M.P.A. certificate, and every effort is made to encourage a high standard of nursing, but the universal difficulty in obtaining satisfactory probationers has been experienced.

The ninety-fifth report of the *Belfast Mental Hospital* is illustrated with photographs showing the excellent system of 11 "villas," in which 1000 patients are housed, according to their condition. The recovery-rate for the year was 24 per cent. and the death-rate 7 per cent. There is rather a high proportion of cases of general paralysis (24 males and three females), which accounted for 17·5 per cent. of the deaths. The malarial treatment has continued to prove satisfactory; out of 48 cases treated, 14 were discharged, 12 were well improved, 8 slightly improved, and 6 died. There have been slight outbreaks of influenza and typhoid fever, rapidly checked by isolation. The typhoid has now been traced to the water-supply and a filtration plant installed. Parole and home visits are allowed wherever possible, and there has been no abuse of the privilege; 60 per cent. of the patients are usefully employed on the farm or in the workshops or wards. A new lending library has been formed, and the "tuck shop" gives innocent pleasure.

The *Monmouthshire Asylum* at Abergavenny supports 1140 patients. The present accommodation is not sufficient to allow of satisfactory segregation, although the system of small dormitories allows classification within wards. The recovery-rate was 40·8 per cent., a great improvement on previous years. The death-rate was 6·2 per cent., and there was no epidemic disease except a few cases of influenza. The dietary has been considerably improved. The dentist has been busily employed, but this institution has at present no specialist visiting staff. An instructor is to be engaged this year for those likely to benefit from physical exercises. Every effort is made to find employment for all patients. Forty-two nurses and attendants hold the M.P.A. certificate. All the visitors remark on the contented and domestic atmosphere of the wards.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED OCT. 17TH, 1925.

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 43; scarlet fever, 2382; diphtheria, 1145; enteric fever, 59; pneumonia, 758; puerperal fever, 36; cerebro-spinal fever, 6; acute poliomyelitis, 10; acute polio-encephalitis, 3; encephalitis lethargica, 56; continued fever, 1; dysentery, 5; ophthalmia neonatorum, 86. There were no cases of cholera, plague, or typhus notified during the week.

Deaths.—In the aggregate of great towns, including London, there were 4 deaths from enteric fever, 26 from measles, 17 from scarlet fever, 29 from whooping-cough, 28 from diphtheria, and 47 from influenza, as compared with 57, 51, 41, and 26 in the preceding weeks. In London itself there were 7 deaths from diphtheria, 2 from whooping-cough, and 10 from influenza, as compared with 12, 9, 5, and 7 in the preceding weeks.

"Audi alteram partem."

ACTIVE IMMUNISATION AGAINST DIPHTHERIA.

To the Editor of THE LANCET.

SIR,—I have pleasure in discussing in more detail the matter dealt with in your annotation of Oct. 3rd. The Austrian Ministry of Health, in response to my suggestion, has recommended that the sale of toxin-antitoxin mixture for active immunisation against diphtheria should not be allowed in Austria. To this recommendation was, however, appended the express condition that the matter should be discussed again, if new methods should be devised, or if such an increase occurred in the number and severity of the cases of diphtheria as to make an active campaign against the disease necessary. Research with new antidiphtheritic methods was not forbidden, only the sale of the preparations.

At present the number of cases of diphtheria is actually so small that the use of intensive measures would not be worth while. We fear that the use, without sufficient grounds, of active immunisation in its present form, which is admittedly not wholly without danger, might compromise all immunisation methods in the public mind, as actually occurred after the recent fatal cases in Baden. Active immunisation is, in any case, not the only means of defence. For the occasional outbreaks of diphtheria of a mild type, with which we have here to do, we find the passive immunity conferred by antidiphtheritic serum entirely satisfactory.

The wish to offer opposition to scientific methods is, needless to say, far from me, for it is just in the prevention of infectious disease that I have always been particularly interested. You will not forget that in your own country the best and most satisfactory of all immunisation methods, that of Jenner himself, is not universally accepted. By pushing the use of methods that have not been fully worked out, one only gives material for opposition to that unscientific section which makes capital out of every failure.—I am, Sir, yours faithfully,

Dr. CLEMENS PIRQUET,
Director of the University Children's Clinic, Wien.
Oct. 21st, 1925.

STANDARDISATION OF BACTERIAL VACCINES.

To the Editor of THE LANCET.

SIR,—In a review of Kolmer and Boerner's "Laboratory Diagnostic Methods," published in THE LANCET of Sept. 19th, p. 606, attention is paid to the nephelometric method of standardising bacterial suspensions, and a preference is expressed for the method of McFarland as compared with that of Brown and Kirwan. The latter was published in the *Indian Journal of Medical Research* in 1915, and was subsequently elaborated in the same journal by the writer in 1919. The main difference between McFarland's method and the other is that in his no allowance is made for the fact that certain organisms are more translucent than others, and the opacity of a certain tube containing a suspension of barium sulphate is stated to be approximately equal to the opacity of a certain definite number of bacteria. In the former paper (Brown and Kirwan, 1915) it was shown that the numerical equivalent of bacterial suspensions of the same opacity varied according to the particular organism under observation.

In my second paper special attention was directed to the fact that the numerical equivalent of bacterial suspensions varied considerably according to the method of standardisation, and I therefore urged that vaccines should be expressed as containing a certain definite weight of dried bacterial substance, a table being given correlating the opacity with the weight of dried bacterial substance for the organisms commonly used in vaccine therapy. Although the dosage of tuberculin has always been expressed in terms of weight, the custom of expressing vaccines in terms of weight instead of number has not come into common use. Cunningham and Timothy realised that a correlation between the opacity and the numerical content of vaccines in common use would probably be more popular than that between weight and opacity, and in a very exhaustive piece of work[1] they correlated, by means of hæmocytometer counts, the number of organisms corresponding to the opacity of the barium sulhpate tubes introduced by Kirwan and myself. These observers performed not less than 30, and, in some instances, as many as 100 counts of 80 small squares for each organism, the readings and opacity values being estimated by the two observers separately. Their findings, therefore, are of extreme value. One very noticeable feature of their results is that for the same opacity there are 2·9 times as many cholera vibrios and three times as many *B. influenzæ* (Pfeiffer) as there are *B. coli*, and other bacteria, too, differ in this respect. This is only what one would expect if in the case of the cholera vibrio the translucency of the organism, and, in the case of *B. influenzæ*, the size is taken into account.

Now both these organisms are commonly used in the manufacture of vaccines, and therefore it would seem that the method of standardisation advocated by McFarland is capable of giving at least a 300 per cent. error if no allowance is made for the variations in opacity produced by the same numerical equivalents of a vaccine per unit volume. Regarding the comparative simplicity of the two methods, in the one which we advocate there are ten tubes containing varying dilutions of barium sulphate, the opacity of which is compared with a similar tube containing the vaccine; the result is then read either in terms of weight of dried bacterial substance per cubic centimetre or by means of Cunningham and Timothy's table as number in millions per cubic centimetre, as counted by the hæmocytometer method. The procedure of standardising vaccines by this method can easily be accomplished in three minutes. It, therefore, cannot be considered complicated, and with the help of Cunningham and Timothy's table it is hoped that one man's million will no longer be another man's thousand.—I am, Sir, yours faithfully,

H. C. BROWN,
Major, I.M.S. (retd.).
Wellcome Bureau of Scientific Research, Oct. 15th, 1925.

AWARENESS OF THE BODY SURFACE.

To the Editor of THE LANCET.

SIR,—Normally, one is only aware of the surface of the body when attention is drawn to it, or when one thinks about a special part. The receptors of the superficial parts of the body have a threshold of resistance that unless a stimulus for which they are adapted occurs, such as pain, touch, or temperature, no sensations arise. By usage we come to neglect the ordinary stimuli caused by clothing, &c., and we are not aware of it unless some special discomfort arises. Hence, awareness of the body surface does not normally occupy consciousness. I have recently seen a case where the patient complained of excessive "awareness" of the surface of the body.

The patient, an intelligent woman of 52 with a neurotic temperament, complained that she became tired on doing a slight amount of work, and that she had to lie down for the greater part of the day. She slept badly, was subject to fits of depression, and felt that she could take no interest in anything. On questioning her, she said that for some time she has had this uncomfortable sensation of awareness of the presence of every part of the surface of her body. She said that this seemed to occupy her whole consciousness and prevented her from concentrating on anything. The sensation was worse on the body and limbs, and least on the hands, feet, and face. She did not complain of pain although she said that she bruised readily. On examination she had a very marked diffuse panniculitis affecting practically all the subcutaneous tissue. Some parts were tender on pressure, and here fibrous nodules were present, but in the main the condition seemed to be a diffuse infiltration of the subcutaneous tissues. The skin could not be picked up in a fold and it was tightly adherent to the subcutaneous fat. Any handling of it gave rise to a sensation of soreness, and left a bright red flush which lasted for a considerable time.

---

[1] Indian Journal of Medical Research, 1924, p. 1253.

The generalised thickening of the subcutaneous tissues will involve the superficial nerves, and they are bound down by the inflammatory tissue to the skin and to the muscular aponeuroses. The continual slight movements present in muscles in a state of postural tone will stimulate the nerves embedded in this tissue, and stimuli will be constantly entering the nervous system from all parts of the body surface affected by the condition. There is probably, in addition, a susceptible state of the nervous system, or a condition of lowered resistance to stimulation. From this arises the consciousness of the different regions of the body surface. It is easy to understand that this continual awareness of the body surface would occupy a large part of the conscious field, and render concentration on anything almost impossible.

This case is of interest as showing the physical basis for what would at first appear to be merely a neurotic manifestation.

I am, Sir, yours faithfully,
Hector M. Walker, M.D.
Harrow, Oct. 15th, 1925.

PIONEERS IN TROPICAL MEDICINE.

To the Editor of The Lancet.

Sir,—With reference to the very kind annotation in The Lancet for Oct. 24th of my presidential address on the above subject to the Royal Society of Tropical Medicine and Hygiene, may I, in justice to the memory of a great and good man, point out that I did not describe Sir John Pringle as pursy and peppery? I said he looked pursy and peppery in his portrait. This is a very different matter, for portraits, especially reprints of portraits painted in the eighteenth century, may not always give a correct reproduction of the original. As a matter of fact I went on to show that Pringle's portrait belied his character, for he was in every respect a very fine man, and there is no indication that he was either peppery or pursy, although, as I said, there was plenty to make him peppery! I should also, perhaps, state that George Biddy of your annotation should be George *Bidie*, this being the way in which the distinguished surgeon-general of the Madras Presidency spelt his name. Benjamin Rush no doubt did his best to quell the outbreak of yellow fever in Philadelphia in 1793, though, in the absence of precise knowledge as to its method of spread, he could not accomplish very much in this direction, but his chief claim to fame is that, during that epidemic, he formed the opinion that the disease was not contagious.

I am, Sir, yours faithfully,
Andrew Balfour.
London School of Hygiene and Tropical Medicine,
Endsleigh-gardens, N.W., Oct. 23rd, 1925.

⁂ Pringle's magnificent services to medicine and in particular to military hygiene could not have been rendered unless his face had belied him. He was in many ways far in advance of his time, and may be said to have foreshadowed the Geneva Convention of our own day. Although Benjamin Rush had no exact knowledge as to how yellow fever was spread, his belief that it was the result of filth in the streets of Philadelphia was so faithfully proclaimed as to cause the greatest anger among the citizens, and incidentally to clear up the nuisance. We are glad to learn that Dr. Balfour's informing address will be available in full in the *Journal of Tropical Medicine and Hygiene* when it appears. —Ed. L.

X RAYING OF TEETH: THE LATEST CRAZE.

To the Editor of The Lancet.

Sir,—Have any of your readers, whose patients' teeth have been X rayed, ever received a report that there was nothing amiss with the teeth? Judging by my experience, everyone whose apparently sound teeth are X rayed is said to have diseased ones. Two of my patients recently went to an oculist. He had their teeth X rayed. A patient went to an aurist and one to a laryngologist; they had their teeth X rayed also. The verdict in each case was that several teeth ought to be extracted. All these patients had more or less recently seen their dentists, who had found nothing wrong with their teeth. One can only wonder how any of the lower classes can see or hear or smell! This tooth-extracting mania seemed to be a good deal on the wane, chiefly, I take it, because doctors with the largest experience of "rheumatic" conditions thought it had been greatly abused. But since this X raying of teeth came into fashion the madness is worse than ever. I am informed that continental medical men do not attribute anything like the same importance to the condition of the teeth as we do, and think we have gone crazy on the subject. I am disposed to agree with them.

I am, Sir, yours faithfully,
Cadogan-place, S.W., Oct. 20th, 1925. Gould May.

⁂ On another page we review a very important book by Dr. Weston Price, of Cleveland, Ohio, which deals exhaustively with the fallacy of judging the degree of dental infection simply from study of a radiogram. The existence of apical rarefaction is not enough to condemn a tooth and he refutes the assumption prevalent in America, that these rarefied areas denote a menace to general health proportional to the degree of bony absorption.—Ed. L.

HOSPITALS, GENERAL AND SPECIAL.

To the Editor of The Lancet.

Sir,—I have read with much interest Mr. Bishop Harman's article in The Lancet of Oct. 17th. I would like, however, to correct him on one point. Mr. Harman writes: "There is at Charing Cross in London a large general hospital with its own eye department and next door to it there is an eye hospital." As a matter of fact, there is no eye department at Charing Cross Hospital. Some few years ago a working arrangement was come to between the Royal Westminster Ophthalmic Hospital and Charing Cross Hospital by which the latter closed its eye department, small as it was, and the few patients on its books were transferred to this hospital. The staff of this hospital undertook to teach ophthalmology to the students of Charing Cross Hospital Medical School (last year 43 students attended the practice), and a member of the staff was appointed a lecturer to their medical school. In exchange we can call upon their general staff to treat our patients apart from eye diseases, and, if necessary, our in-patients who develop complaints other than "eyes" can be transferred to Charing Cross Hospital for in-patient treatment. Thus there is the daily contact between the specialist and the general surgeon and physician which Mr. Harman advocates. We have here two institutions, working side by side, each carrying on its separate sphere of work in an efficient manner.

As a lay officer to a special hospital of nearly 30 years' experience I may be biased, but I am of opinion that our general hospitals, as at present constituted, could not possibly cope with the vast influx of "special" patients. For instance, in 1924 the five ophthalmic hospitals of London treated 107,792 out-patients, representing 271,819 attendances, with a total of 222 occupied beds. They could not be absorbed in general hospitals. Moreover, the patient is a factor that must be taken into account. It is an undoubted fact that in this age of specialism the patient prefers to go to a special hospital, dealing solely with the complaint from which he may be suffering, whether it is eyes, nose and throat, and so forth.

Again, the special departments of our general hospitals are nothing like so well equipped as the special hospitals. Generally speaking, patients can only attend once or twice a week at the most, against a daily attendance in a special hospital, and taking "eyes" alone, I know of general hospitals where the eye specialist is lucky if he can get six beds set apart for his use. The whole question, if I may use the expression, boils down to the point, What do the patients want? And the answer is that so long as the special hospitals carry on their work in an efficient manner, keeping abreast with the times, so long will they be in demand by the public.

I am, Sir, yours faithfully,
J. H. JOHNSON,
Secretary, Royal Westminster Ophthalmic Hospital, W.C.
Oct. 19th, 1925.

*** We have submitted Captain Johnson's letter to Mr. Harman, who writes: "The change in the arrangements between the Royal Westminster Ophthalmic and Charing Cross Hospital was not known to me. I had in mind the time when Mr. Treacher Collins was the eye surgeon at the latter hospital. But the point, had I known it, would only have made me the more able to drive home the lesson I was striving to bring out. That the R.W.O. Hospital and the general hospital next door have a working arrangement is the better plan and that which I stated was coming into play in place of which I had information."—ED. L.

RESPIRATORY CATARRH IN CHILDREN.

To the Editor of THE LANCET.

SIR,—It is most cheering, for such views are still rare, to read Dr. R. C. Clarke's article in your issue of last week, in which he recommends, as a preventive for nasal catarrh, that children should live in the open air or in a draught. I can endorse his experience that under such conditions they do not suffer inconvenience from feeling cold. My own children, when not out of doors, live and sleep in draughts in all weathers, and I have been surprised to find how little clothing they require for warmth and comfort. They never "catch cold" unless brought into contact with people suffering from nasal catarrh, and this chiefly when school life begins. One would like to see all schools built for open-air life on the lines of the hospitals being erected for the treatment of tuberculosis and rickets by direct sunlight.

With regard to babies being bathed in a room with the windows open, I think that mothers and nurses who fear the danger of exposure to cold should be reminded that they leave out of calculation the time element. A baby left naked on the lawn all night will be found dead in the morning, but the effect of cold moving air on the bare skin of a healthy kicking infant for five minutes will only have a bracing effect.

I am, Sir, yours faithfully,
IVY E. HASLAM, M.D., M.R.C.P.
Bromley, Kent, Oct. 26th, 1925.

PREMATURE BURIAL.

To the Editor of THE LANCET.

SIR,—The possibilities of premature burial under existing circumstances are extremely remote, but the mere fact that such a possibility exists is a matter of grave import to the peace of mind of many of the living, as evidenced by the periodical recurrence of the question, which so far has elicited no definite solution. I cannot but think, however, that if the following suggestion were generally adopted as part of the preparation for burial, there would be no further need for any anxiety on this score.

The coffin should be made deep enough for the body, when in situ, to be an inch and a half to two inches below the level of the rim. A thick layer of sawdust is spread at the bottom of the coffin, banking up towards the sides, and on this the lightly clothed body is placed. Then some 12 hours before the coffin is closed down it should be filled carefully with sawdust up to the level of the rim, the face having been previously covered with a soft fabric. It must be seen to that the sawdust fills every interstice around the body, and that it is well and thoroughly pressed down. The coffin is then left without the lid. A special face cloth could be devised reinforced in the part that would cover the mouth and nostrils, so that in case of a sudden gulp the fabric should not form wedge or rupture.

I think it is safe to say that however slow the ebb of life, however deep the state of attenuated animation, no human being, thus hermetically isolated, could live for an hour, probably not for 15 minutes, without that struggle for air being brought about which would cause the person to raise himself up and be restored to the freedom of life.—I am, Sir, yours faithfully,
L. VINTRAS,
Consulting Physician to the French Hospital.
Oct. 21st, 1925.

LUMINAL, BORAX, OR BROMIDE IN EPILEPSY.

To the Editor of THE LANCET.

SIR,—May I suggest that the value of Dr. C. Worster-Drought's prescription for epilepsy (sodium bromide and sodium biborate) might be enhanced in the case of some patients at least, by the addition of, say, ten drops of the tincture of nux vomica? Probably the best routine mixture for epilepsy is one containing these three drugs. I do not advocate the addition of arsenic as a matter of routine, as some patients can take considerable quantities of bromide for years without suffering any serious inconvenience from pustules. As to the value of luminal, either alone or in addition to the bromide mixture, there can be no doubt. Only by carefully experimenting is it possible to discover the most suitable combination of drugs and their dose for individual cases.

I am, Sir, yours faithfully,
Harley-street, W., Oct. 26th, 1925. HARRY CAMPBELL.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comdr. W. E. Ormsby is placed on Retd. List with the rank of Surg. Capt.

Surg. Capt. H. S. Burniston is placed on the Retd. List with rank of Surg. Rear-Admiral.

ROYAL ARMY MEDICAL CORPS.

Maj. E. M. J. O'Farrell to be Temp. Capt. and temporarily relinquishes the rank of Maj.

Lt. W. Boyd, late R.F.A. (Spec. Res.), to be Lt.

MILITIA.

Maj. H. H. Brown relinquishes his commn. and retains the rank of Maj.

TERRITORIAL ARMY.

Capt. R. C. Aitchison (R. of O.) to be Maj.

Supernumerary for Service with the O.T.C.—Majs. G. A. Williamson and H. Emerson resign their commns. and retain their rank.

Lt. C. J. A. Woodside resigns his commn. and is granted the rank of Capt.

Lt. R. E. Holme to be Lt.

ROYAL AIR FORCE.

R. J. K. Chattey is granted a short service commission as a Flying Officer for three years on the Active List.

INDIAN MEDICAL SERVICE.

Lt.-Col. A. Fenton to be Col.

Majs. B. E. M. Newland, L. A. H. Lack, Narendra Singh Sodhi, and W. C. Gray to be Lt.-Cols.

The Admiralty have published the limits of the promotion zones for the half-yearly advancements of commanders in the medical branches of the Service. Surgeon-commanders must be of eight years' seniority and over on the date of selection.

Medical News.

University of London.—At a meeting of the Senate held on Oct. 21st, Prof. E. A. Gardner, the Vice-Chancellor, being in the chair, the following bequests were accepted: From the late Sir Rickman Godlee, Bt., a legacy by which, after the death of his wife, one moiety of his residuary estate is given to University College and the other moiety of his residuary estate to University College Hospital. From the late Miss L. S. Gibbs, in memory of her mother, the sum of £150 per annum to be devoted to the establishment of a studentship, to be called "the Laura de Saliceto Studentship," for the advancement of cancer research, either on the physiological or the chemical side.

The Semon Lecture: University of London.—Dr. Patrick Watson-Williams (of the University of Bristol) will deliver a lecture on the Toll of Chronic Nasal Focal Sepsis on Body and Mind in the Lecture Hall of the Royal Society of Medicine, 1, Wimpole-street, W., on Thursday, Nov. 5th, at 5 P.M. The chair will be taken by Sir William Milligan. A reception will be held at 4.30 P.M., prior to the lecture.

Royal College of Surgeons of England.—The Bradshaw Lecture will be delivered on Nov. 11th by Mr. James Sherren, the subject being Gastro-jejunostomy, and the Thomas Vicary Lecture on Nov. 18th by Prof. William Wright, who will take for his subject the Mediæval Conception of the Anatomy and Physiology of the Central Nervous System. Both lectures will begin at 5 P.M.

Queen Charlotte's Maternity Hospital: Post-graduate Lectures.—The following series of post-graduate lectures will be delivered at Queen Charlotte's Maternity Hospital, Marylebone-road, N.W., during November and December on Thursdays at 5 P.M.: Nov. 5th, Mr. A. W. Bourne, Common Obstetric Difficulties; Nov. 12th, Mr. T. Stevens, Meddlesome Midwifery; Nov. 19th, Mr. T. B. Davies, Clinical Aspects of Abortion; Nov. 26th, Mr. L. Roberts, Conditions Leading to Obstructed Labour; Dec. 3rd, Mr. L. C. Rivett, Antepartum Hæmorrhage; Dec. 10th, Mr. L. Phillips, The Failed Forceps Case; Dec. 17th, Mr. Leslie Williams, Albuminuria of Pregnancy.

Joint Tuberculosis Council: Post-graduate Courses.—During September two courses of study in tuberculosis were arranged by the council in consultation with the Ministry of Health, as follows:—(1) A course of two weeks' duration in the pathology and bacteriology of tuberculosis conducted by Dr. Roodhouse Gloyne at the City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, limited to six members. (2) A course in non-pulmonary tuberculosis of one week's duration. Demonstrations were held during the week at Heatherwood Hospital, Ascot; Queen Mary's Hospital, Carshalton; the Dermatological Department of the London Hospital; the Royal College of Surgeons; All Saints Hospital for Genito-Urinary Diseases; Wingfield Orthopædic Hospital, Oxford. The class was limited to 30 members. The courses were very well attended and it is the intention of the Joint Tuberculosis Council to arrange post-graduate courses to be held in 1926. A syllabus will be issued in January.

Fellowship of Medicine and Post-Graduate Medical Association.—Dr. J. Campbell McClure will lecture for the Fellowship of Medicine on Monday, Nov. 2nd, at 5.30 P.M., in the Lecture Hall of the Medical Society of London, 11, Chandos-street, W. His subject will be the Climatic Treatment of Tuberculosis, and all members of the medical profession are welcome to attend. Throughout the month of November the London Lock Hospital will hold a comprehensive course dealing with the Study of Venereal Disease, and as the course is only held if there be a sufficient entry early application is requested. There will be a three weeks' course in Gynæcology at the Chelsea Hospital for Women from Nov. 2nd to the 21st, consisting of demonstrations in the theatre, wards, &c. From Nov. 3rd to the 28th Dr. Porter Phillips and Dr. Thomas Beaton will give twice weekly lecture-demonstrations on Psychological Medicine at the Bethlem Royal Hospital. At the Victoria Park Hospital a course will be held in Diseases of the Chest from Nov. 9th to the 21st. From Nov. 23rd to Dec. 12th the Royal Waterloo Hospital will hold a course in Medicine, Surgery, and Gynæcology, embracing the various departments pertaining to diseases of women and children. A late afternoon course (4.30 to 6 o'clock) will take place at the London Temperance Hospital from Nov. 23rd to Dec. 4th for the benefit of the general practitioner. Copies of the syllabus of these courses, as also the general programme, may be obtained from the Secretary to the Fellowship of Medicine at 1, Wimpole-street, London, W. 1.

Royal College of Physicians of Edinburgh, Royal College of Surgeons of Edinburgh, and Royal Faculty of Physicians and Surgeons of Glasgow.—The following candidates have passed the Triple Qualification Examination:—

FINAL EXAMINATION.

Alistair G. Cruikshank, Kristian Skulberg, Ian E. Dirckze, William A. F. Hurst, Jack Greenstein, Cecil J. R. Morrison, Nathanael J. Knoesen, William A. N. Chanmugam, Archie N. Tong, Isadore Kovolman, Cheng Leng Tan, David Lumsden, Thiam Hock Wee, Coruvakankanage Don Martinus Madappuli, Alfred A. Labinjoh, David D. H. Craig, Irma E. L. Law, Joseph W. McVicker, James Hasson, Constance C. Reid, Ella D. Messenger, John S. Whiteside, Thomas W. Chapman, Cassaly Ismail, John R. Hetherington, Appacuttiar B. C. Doray, Jack Cohen, Mary A. McGill, Tom G. S. Harkness, Louis G. Blaze, Albert E. Williamson, George R. Mitchell, and Arumugam Wyramuttoo Rasiah.

Medicine.—James K. Steel, Robert H. McKinnon, and Marian E. Owen-Morris.

Surgery.—Robert W. Schuch, William McKim, and James W. Wylie.

Midwifery.—James K. Steel, Collin H. Wickremesinghe, Moss M. Bronstein, Robert W. Schuch, William McKim, Joseph B. Stromier, James W. Wylie, John L. Dearberg, Alexander Rankin, Asit Chandra Bagchi, Charles E. Millen, Catherine Millar, and William T. Baker.

Medical Jurisprudence.—John J. Gilchrist, Manikkathuppahige Thosius Fernando, Stephen B. Stoker, Arthur G. Young, Abdalla Abdel Razzak, Labib Abdel Malik-Mansour, Ian G. Sutherland, George R. Day, Ronald A. Paton, Thomas G. McIntyre, Thomas B. Dobson, Archibald Maxton, Alexander S. Speirs, Maud Heaton, William B. Anderson, John T. W. Gale, John Williams, Gwendoline R. Andrews, James Hendry, William Read, and William W. McGlashan.

DIPLOMA IN PUBLIC HEALTH.

Edwin D. M. Wallace, Malcolm J. Miller, Violet Oswald, Charles Melville, Elizabeth W. Miller, Marjorie H. Mitchell, George A. Pollock, William R. Logan, Jeanie M. Strathie, Jane T. Gilmour, Elsie B. Dickinson, and William B. Watson.

Part I.—George B. Walker, David Robertson, John H. D. Lawrie, David W. C. Tough, Ralph S. Begbie, Desmond S. Malone, Jacobus Johannes de Waal, and Khwaja Samad Shah.

Part II.—Jessie G. Service.

Royal College of Surgeons of Edinburgh.—At a meeting of the College on Oct. 21st, Dr. Arthur Logan Turner was elected President for the ensuing year, Sir David Wallace Vice-President, and Mr. Alexander Miles Secretary and Treasurer.—Mr. David Middleton Greig was awarded the Liston Victoria Jubilee Prize of £100 in recognition of his contributions to practical surgery and surgical pathology.—The following 28 successful candidates, out of 61 entered, who passed the requisite examinations between July 6th and 13th, were admitted Fellows:—

James C. Anderson, Jack R. S. G. Beard, John M. Black, Cecil R. Childs, Bruce M. Dick, Charles S. Fraser, Robert L. Galloway, Israel Goldberg, Robert Grant, John D. Grierson, Dorothy W. Hall, Frederick J. S. Hall, Oscer M. Irwin, Harold W. Johnston, Matilda John, Philip C. Livingston, William J. Macdonald, Harold J. Malkin, Subodh Mitra, John S. Moore, Chandiram H. Primlani, Arnold R. Richards, James H. Robertson, Ronald G. Shackleton, John H. Shaw, Maurice Sourasky, Denis B. Whitlock, and Arthur C. K. Yates.

Dr. Einer Wesley Johnson U.S.A., having passed the requisite examination on Sept. 30th, obtained the diploma of Licentiate of the College.

At recent examinations, out of 20 candidates entered, the following 14 passed the Final Professional Dental Examination and were granted the diploma L.D.S. R.C.S. Edin.:—

John Baker, Philip Henry, Roberta J. T. Morris, Jean Y. Andrew, Henry W. Bambridge, Andrew S. Irving, William C. Archibald, George M. Brown, Noel A. Reid, Evelyn Richardson, Dorothy J. O. Mitchell, Malcolm McDonald, Leslie V. Sherrin, and Harry W. Stewart.

The following candidates passed in the subjects indicated:—

Pathology.—Thomas T. Jamieson, Hector Archibald, and John E. McNicol.

Medicine.—Thomas T. Jamieson and Herbert F. Simpson.

Surgery.—Hector Archibald and John E. McNicol.

Royal Commission on National Health Insurance.—The forty-second meeting of the Commission was held at the Home Office, Whitehall, on Oct. 22nd and 23rd, Lord Lawrence of Kingsgate being in the chair on the 22nd and Sir Arthur Worley on the 23rd. Evidence was given by Mr. J. G. F. Price, Principal Assistant Secretary, Ministry of Labour, on the question of utilising the employment exchanges to certify genuine unemployment for the purpose of dealing more generously with the problem of the arrears penalties under the Health Insurance Scheme. Thereafter Sir Walter Kinnear, Controller of the Insurance Department of the Ministry of Health, Mr. L. G. Brock, Principal Assistant Secretary, and Dr. J. Smith Whitaker, Senior Medical Officer of the Ministry, were examined on a wide range of questions affecting Health Insurance on its administrative and medical sides.

ROYAL SOCIETY OF ARTS.—The next session of this society will be opened on Wednesday, Nov. 4th, at 8.30 P.M., at John-street, Adelphi, London, W.C., when the inaugural address will be delivered by Sir Thomas H. Holland, F.R.S., Chairman of the Council, the subject being the Organisation of Scientific Research Throughout the Empire.

MEDICAL PRACTITIONERS UNION.—A Special Conference on Disciplinary Procedure under the Health Insurance Acts was held by the Union at the Russell Hotel on Oct. 21st. At the afternoon sitting there was an attendance of about 35, and about 20 local medical and panel committees sent representatives. At the close of the proceedings these representatives, together with the chairman (Dr. A. E. Gregg), the secretary (Dr. A. Welply), Dr. Gordon Ward, and the solicitor to the Union (Mr. S. G. Davis), were appointed to form a deputation to lay before the Minister of Health the following resolutions passed at the Conference :—

Proceedings Prior to Hearing.—This Conference is of opinion (*a*) that when comments are invited from a doctor in order to facilitate a decision as to whether a formal hearing is desired the invitation should be accompanied by a warning that the comments supplied are likely to be considered by two statutory committees, and may form the basis of a demand for disciplinary action by the Minister ; (*b*) that before a hearing is arranged, any charge against a doctor should be defined in writing and should state in every case which of the regulations or terms of service is alleged to have been infringed and in what respect the same have been infringed ; and (*c*) that the rules relating to complaints are now so generally known that ignorance of them should no longer be allowed as an excuse for delaying notice of a complaint for more than six weeks after the event in which it originated.

Medical Service Subcommittee.—This Conference is of the opinion (*a*) that the proceedings of the Medical Service Subcommittee should be strictly confined to the charge already formulated ; (*b*) that a medical service subcommittee ought not to found its report, in whole or in part, on evidence to which the practitioner concerned has had no opportunity to reply ; and (*c*) that medical service subcommittees are not suitably constituted for the determination of scientific questions such as frequently come before them.

Removal from Panel.—This Conference is of the opinion (*a*) that successful defendants in these proceedings should be given costs as against the Insurance or other complainant committee on the same scale as those awarded the latter when the doctor's plea fails ; (*b*) that there is nothing in the regulations which can excuse the action of the Ministry in withdrawing from the purview of inquiry committees the right to draw inferences of fact as to the question of a practitioner's fitness to remain on the panel ; (*c*) that the action of the Minister in permitting inquiry committees to refuse evidence of general good repute is entirely indefensible on moral or legal grounds. This Conference protests against the action of the Ministry in hearing evidence which has come to hand subsequently to the sitting of an inquiry committee and which the practitioner can neither know of nor obtain opportunity to rebut. Particular objection is taken to the hearing in this manner of expert evidence tendered in opposition to the practitioner.

Procedure on Appeal.—This Conference is of the opinion that (*a*) appeal tribunals should be composed of absolutely independent persons not identified in any way with the administration of the National Health Insurance Acts ; (*b*) that an appeal tribunal should hear the case de novo and should not have before it any evidence not taken on oath, or otherwise not properly admissible in a Court of Law ; (*c*) that the Minister's decision should be such as is consistent with the report of the Appeal Tribunal ; (*d*) that the report of the Appeal Tribunal should be promulgated within seven days of the conclusion of the hearing ; and (*e*) that the decision of the Minister following appeal or after hearing of representations should be given within one week after the promulgation of the report.

General.—(*a*) This Conference is of the opinion that the standard of service contemplated by the National Health Insurance Acts is the standard enforced by the Courts and no other, and protests against the action of the Ministry in setting up a different standard. (*b*) This Conference calls attention to the great expense in time and money to which a practitioner may be put in defending himself on the same charge before three different tribunals—namely, the Minister, the General Medical Council, and the ordinary courts. (*c*) This Conference recommends that the medical benefit regulations should provide for a general right of appeal to the courts. (*d*) This Conference is of the opinion that the evidence given before it affords ample witness to the injustice of much of the procedure relating to complaints both in theory and in many particular instances, and strongly recommends to the Minister the setting up of a committee, including representatives of this Conference, to report what alterations are desirable.

INSTITUTION OF HEATING AND VENTILATING ENGINEERS.—On Wednesday, Nov. 4th, at 7 P.M., a paper on the Modern Development of Combustion Recording will be read by Mr. J. J. Lassen at Caxton Hall, Caxton-street, Westminster, S.W.

BRITISH MEDICAL ASSOCIATION : COUNCIL DINNER. The fourth annual Council dinner of the British Medical Association was held on Oct. 21st in the Great Hall of the new B.M.A. House, and Dr. R. A. Bolam, who was in the chair, spoke of the pleasure which it gave the officers of the Association to be able to entertain their guests in their own house. The toast of the " Retiring President," proposed with humour and feeling by Sir Richard Luce, gave Mr. J. Basil Hall the opportunity to describe some of the incidents of two happy and busy years. As ambassador for the Association to the Canadian Medical Association and the American Medical Association Mr. Hall had made a happy impression on the other side of the water by his tact and native wit. The " Common Health " was proposed by Sir Thomas Horder, who sketched the diminished mortality of the last 25 years and remarked on the training in preventive medicine obtained by 14,000 panel practitioners who for 12 years past had practised on a system by which they were paid better when their patients were well than when they were ill. He voiced the need for a properly equipped and well-staffed post-graduate school, and concluded an eloquent speech with the three words—education, organisation, coöperation. Captain O. E. Warburg, the Chairman of the London County Council, spoke of the fulfilment of the Council's aim to coöperate with the medical profession in the conduct of school and special clinics. Mr. S. P. Vivian, Registrar-General, also responded. Mr. E. B. Turner, in proposing " Our Guests," specially welcomed two distinguished visitors from South Africa, Dr. W. Watkins-Pitchford and Dr. A. J. Orenstein. Sir Kingsley Wood, who responded, spoke of progress in national health as due largely to a partnership between the State, the local authorities, the medical profession, and the great voluntary agencies. He was himself a believer in voluntary health service ; too many people, he thought, were looking to the State for things that they ought to be doing themselves. Voluntary effort was the pride of this country and the general practitioner the backbone of medical organisation. Sir Holburt Waring, who also replied, hoped soon to see an amendment to the Medical Act whereby treatment of disease was limited to men having a proper medical education. Dr. C. E. Douglas proposed " The Chairman," and Dr. Bolam, in responding, foreshadowed his intention shortly to retire from the onerous position which he has ably filled for so long. Dr. Alfred Cox was incited to speak a few words regarding his impending visit to South Africa. An admirable programme of music filled in the intervals.

AT a general meeting of the Surrey branch of the British Medical Association (Kingston-on-Thames Division), to be held at Surbiton Hospital on Tuesday, Nov. 3rd, at 8.45 P.M., an address will be delivered by Dr. Norman Haire on Birth Control and Contraceptive Methods.

ORTHOPÆDIC AFTER-CARE.—As the outcome of the work of the Shropshire Orthopædic Hospital and the Agnes Hunt Surgical Home at Oswestry, an after-care committee for Shrewsbury and the district has just been formed. From a wooden shelter erected by Miss Agnes Hunt in her garden 25 years ago, orthopædic work in Shropshire has developed until the hospital contains 300 beds. Shrewsbury was the first town in the world to open a clinic for cripples.

LANCASHIRE INSURANCE COMMITTEE AND THE SPAHLINGER TREATMENT OF TUBERCULOSIS.—On Oct. 19th at Preston the Lancashire Insurance Committee discussed at length a recommendation from its Spahlinger Committee that a conference of representatives of insurance, public health, approved society, tuberculosis and panel committees in Lancashire be called with a view to action being taken in regard to the Spahlinger treatment for tuberculosis. A report from Dr. G. L. Cox, county tuberculosis officer, was read, in which Dr. Cox suggested that the only way to solve the question was an extended trial through the Medical Research Council and the Joint Tuberculosis Council for England and Wales and through them by the tuberculosis branch of the public health service. A letter was read from the Ministry of Health, dated Oct. 31st, 1923, in which, referring to the visit of a deputation from the Lancashire Insurance Committee, it was clearly stated that the committee could not spend money from its funds on an inquiry into the treatment. Ultimately the committee passed a resolution that a meeting of representatives of the various committees in the county interested be called to hear addresses with a view to their reporting to their respective committees.

Royal Society of Medicine.—Commencing on Tuesday, Nov. 3rd, the Library of the Royal Society of Medicine will be kept open until 10 P.M. on two evenings of the week—namely, Tuesdays and Fridays.

London Hospital Medical College. — The Schorstein Memorial Lecture will be delivered by Sir Humphry Rolleston on Friday, Dec. 4th, at 4.15 P.M., in the Anatomical Theatre of the College. The subject will be Lymphadenoma.

Liverpool: Royal Southern Hospital Extension.—A scheme for the erection of an annexe to this hospital is in progress, and it is hoped in the near future to take down some old property at the corner of Hill-street and erect on the site a four-storey building close to the hospital, which would provide extra accommodation for the staff and 20 additional beds for patients.

Hackney Maternity Centre.—The Duchess of York last week opened a maternity and child welfare centre in Lower Clapton-road, Hackney, which, it is hoped, will greatly facilitate work which has been going on steadily for a long time past. So successful has this work been that, although Hackney has a population exceeding a quarter of a million and an average of 5000 births a year, last year it had the lowest infantile death-rate on record.

Cancer Hospital, Fulham-road, London.—The Duke of Connaught last week opened two new theatres which have been provided at this hospital in memory of the late Sir Charles Ryall, who was surgeon there from 1898 to 1922. The theatres, which are on the top floor, are arranged as one unit, so that while one of them is occupied the other can be got ready for another operation. The galleries for the students run from end to end of the building, the anæsthetic rooms and other appurtenances being close at hand. The work involved the construction of a new maids' home, the old one having been absorbed by the alterations. Consequently the cost reached £50,000.

Judgment for Durban Doctor.—Our South African correspondent writes: Before Mr. Justice Carter and a special jury the case was concluded at Durban on Sept. 26th, in which Margaret Scott Ferguson, proprietress of a boarding-house at Isipingo, near Durban, sued Dr. C. D. Relton, of Durban, for £1599 damages for alleged wrongful incarceration in the mental hospital, Pietermaritzburg. A verdict was given for the defendant, with costs. The jury recommended the desirability of establishing an observation ward, to be apart from the mental hospital, so that patients could stay there prior to their removal to the hospital itself. Mr. Justice Carter commented favourably on the jury's recommendation.

Newcastle: Post-graduate Study.—The general course of post-graduate study, which commenced at the Royal Victoria Infirmary on Oct. 1st, is being attended by 51 practitioners. The meetings are held on Thursday afternoons, and instruction is given each day in clinical medicine, clinical surgery and pathology, including post-mortem demonstrations. Three special lectures have been arranged as part of the general course, the first of which, on the Post-Operative Treatment of Tonsils and Adenoids, was delivered by Dr. J. Dunlop Lickley on Oct. 1st. Dr. R. A. Bolam will lecture on Nov. 5th on the Present Day Treatment of Syphilis, and Prof. David Burns will give the third lecture on Dec. 3rd on Insulin. A special course in midwifery and gynæcology is being conducted at the Princess Mary Maternity Hospital by Prof. Ranken Lyle and Dr. E. Farquhar Murray. In addition to these courses, which form part of the routine post-graduate instruction of the University of Durham, an intensive course of a fortnight's duration commenced on Oct. 12th. This course was arranged in conjunction with the Ministry of Health and the Northumberland Panel Committee for the benefit of panel practitioners in the rural areas of Northumberland, and was limited to 12 members, who were selected from the applicants by the Northumberland Panel Committee. The Panel Committee, after careful consideration, elected to expend in this way part of their share of the special £10,000 fund, which was also applied to the provision of locums for the members of the class. A very comprehensive syllabus comprising some 60 lectures and demonstrations was arranged, occupying each morning and afternoon. The first hour of each day was devoted to a course of clinical pathology designed to meet the requirements of general practitioners. The remaining hours were occupied by classes in medicine, surgery, midwifery, gynæcology, eye diseases, diseases of infancy, and so forth, the individual subjects being selected with the object of enabling the members to understand the significance and practical application of recent advances in knowledge. The instruction was essentially clinical, and the limited size of the class facilitated the examination of a large number of cases by each member.

Guest Hospital and Eye Infirmary, Dudley.—The recent bazaar for the liquidation of the debt upon this institution has produced a net profit of £14,117.

The Editor of the "Medical Who's Who" asks us to request all practitioners not having done so to return their forms immediately to 8, Stone Buildings, Lincoln's Inn. The 1926 edition is now going to press, and will, it is expected, be ready early in the New Year.

Rontgen Society.—A general meeting of this society will be held on Tuesday, Nov. 3rd, at 8.15 P.M., in the British Institute of Radiology, 32, Welbeck-street, London, W., when Mr. F. W. Aston, D.Sc., F.R.S., will deliver his presidential address on Atoms and X Rays.

Colwyn Bay Hospital.—The new Colwyn Bay and West Denbighshire Hospital was opened on Oct. 17th by Lord Colwyn. It has developed from the smaller hospital erected about a quarter of a century ago. There are in all 60 beds for patients, the old block being used for administrative purposes. The total cost of the hospital, including the equipment and wiping out of a debt of £440, was £35,285. The receipts towards that sum—including £10,000 from the British Red Cross Society and £19,000 from two garden fêtes—come to a total which leaves a balance of £2500. This sum has now been raised so that the hospital was opened free of debt.

University of Manchester.—*Travelling Fellowship in Psychological Medicine.*—Through the generosity of Mr. Ernest A. Knight, hon. treasurer of the University of Manchester, a selected medical graduate will be enabled, this winter, to visit the United States. His mission will be to study and eventually to report upon the methods used in approved institutions, to investigate the part played by mental factors in the development, treatment, and cure of mental disorders. Should the University so desire, he will be required on his return to deliver an address on the subject of his investigation. The competition was open to those who had obtained or had entered upon a course for the diploma in psychological medicine of the University. It is hoped to announce the award at an early date. The purpose of the Fellowship is that of the Knight Prize, which is offered annually in the University, to encourage the study of psychological factors in the causation and cure of mental disturbances.

Cancer Campaign in Manchester.—At a public meeting held in Manchester on Oct. 23rd, called by the recently-formed Manchester Committee on Cancer, it was resolved to issue an appeal for £20,000 with which "to carry out in Manchester during the next three years an approved scheme of investigation into the disease of cancer." Dr. W. E. Gye, pathologist to the National Institute of Medical Research, was the chief speaker. The appeal was particularly directed to the commercial community to support the fund on the ground that it was one of the best investments anybody could participate in. Dr. Veitch Clark, medical officer of health for the city, said that the committee intended to follow the meeting up by a personal appeal to all whom they thought they could approach with success; but at the same time they wanted to reach the general public and impress them with the importance and urgency of the work and the appeal. The Chairman of the Royal Infirmary Board said his board was whole-heartedly in accord with the scheme.

The late Dr. T. Drysdale.—Dr. Theodore Drysdale, of Cadogan-place, Chelsea, died on Oct. 8th, aged 45. He was born in the Central Provinces of India, and was educated in England at St. Paul's School and Jesus College, Cambridge. He received his medical training at St. George's Hospital, qualifying M.R.C.S. Eng., L.R.C.P. Lond. in 1904, and graduating M.B., Ch.B. Camb. the following year. After holding resident hospital appointments, including that of anæsthetist to the Cancer Hospital, Fulham-road, he went into partnership with the late Dr. Reid, of Sloane-square. A keen and energetic worker, he gradually built up one of the largest private practices in London, specialising to a considerable extent in midwifery. Dr. Drysdale was a prominent athlete. While at Cambridge he gained his Rowing Blue in 1902, won the Colquhoun Sculls in the same year, and obtained his Rugby Football Blue in 1900 and 1901. Throughout his professional life he "kept fit" by playing squash racquets, and represented England *v.* America at this game in 1923. A colleague writes of him: "Dr. Drysdale was a man of great personality, eminently proficient in all branches of his profession, and sound in judgment. He had little time for reading or writing, but, nevertheless, kept himself well up to date with all forms of treatment. He was competent, alert, and above all things loyal, a quality all too rare in these days. Though never in the limelight, to which he objected above all things, his loss, nevertheless, will be felt throughout London."

The death has occurred at Edinburgh of Dr. John Robertson Henderson, C.I.E., F.R.S.E., formerly curator of the Madras Museum and professor of zoology in the Madras Christian College. Dr. Henderson was an authority on Indian crustacea and South Indian numismatics.

West Riding Association of Edinburgh University Graduates.—The annual dinner will be held at the Great Northern Hotel, Leeds, on Wednesday, Nov. 18th, at 7.15 p.m., when Mr. Alexander Miles will be the guest of the association. The dinner will be preceded by a general meeting at 6.30 p.m. Any graduate desiring information should apply to the hon. secretary, 33, Manor-row, Bradford.

Norwood Sanatorium for the Treatment of Inebriety and Drug Addiction.—Dr. Francis Hare has resigned the office of medical superintendent of the Beckenham branch of this sanatorium on grounds of ill-health. His place as medical superintendent at the Mansion, Beckenham Park, Kent, will be taken by Dr. A. W. George, who has been acting as assistant to Dr. Hare. At Rendlesham Hall, the Suffolk branch of the sanatorium, there is a park of 450 acres, containing a private nine-hole golf course.

Doncaster's Open-air School for Defective Children.—The Doncaster Education Committee are about to build an open-air school to accommodate 240 children who are mentally or physically too backward to be taught at the ordinary schools. The children will be under the constant care of the medical officer of health. Rooms for medical examination and treatment will be provided. It is intended to provide the children with midday meals at the school. Both the back and front of the building will be completely thrown open according to the state of the weather and the direction of the wind. Heat will be radiated from the panels of the walls. The school will be provided with about three acres of garden in which the children can play and practise horticulture.

Hospitals and Road Accidents.—In an appeal for money to reduce the debt upon the Hampstead General and North-West London Hospital, it is stated that a large number of motoring and road accidents have been treated during the last few months and that a heavy burden has thus been thrown upon the institution. Commenting upon this statement, Mr. E. W. Morris, house-governor of the London Hospital, points out that the rapidly growing number of accidents of this kind adds seriously to the difficulty of finding room there for the waiting cases, which now number 1100. Mr. Morris adds that if in cases where compensation is paid for street accidents a contribution were made to the hospitals an addition to revenue would be obtained that would enable it to meet the demands of the waiting-list. It is pointed out by a motor-car insurance company that there are occasions when insurance companies do make contributions to hospitals in consideration of their services to injured persons.

The late Dr. E. C. Hinde.—Eric Clark Hinde, M.B., B.S. Lond., who died on Oct. 20th at the age of 30, was educated at Bootham School, York, and entered Guy's Hospital in 1913 with a science scholarship. His studies were interrupted by a period of service with the Friends' Ambulance Unit in Flanders, when he was chiefly occupied with tracking typhoid contacts. After qualifying M.R.C.S. in 1917 he was house physician at the Queen's Hospital for Children in London, and served again in France before taking his London medical degree in 1920. He started in practice, first as assistant and then as partner, with Dr. H. T. Gillett, in Oxford, where he was anæsthetist to the Wingfield Hospital and assistant in the Throat and Ear Department of the Radcliffe Infirmary. In December, 1922, he developed laryngitis, which proved to be tuberculous, and spent the last three years in a consistent, but unavailing search for health at home and abroad. His early death removes an attractive personality and cuts short a career of considerable promise.

Donations and Bequests.—Mr. James Charles Marshall, of Eastbourne, formerly chairman of Marshall and Snelgrove, Ltd., besides other bequests, gave 1000 preference shares in Debenhams, Ltd., to the Cottage Homes, Mill Hill, and 500 such shares each to Middlesex Hospital, the London Fever Hospital, and the London General Porters' Benevolent Association.—Cheques for £1000 were presented to the Lord Mayor of Liverpool from the Liverpool Fruiterers Association for the endowment of beds bearing the names of the chief magistrate and the lady mayoress in the Royal Liverpool Children's Infirmary and the Liverpool Maternity Hospital.—Mr. R. Rees Thomas, of Llanbedrog, Carnarvonshire, has sent a cheque for £1000 in aid of the extension of the Carnarvonshire and Anglesey Infirmary, Bangor.—The Manchester Royal Infirmary has received from the executors of the late Mr. W. H. Armitage a legacy of £1000, and £10,000 on account from the bequest of the late Miss Ann Russell, of Cheetham Hill. Miss Russell left the residuary portion of her estate, amounting to over £100,000, to six Manchester charities.—Mrs. Fanny Davis, Exmouth, left £500 each to Exmouth Cottage Hospital and the Devon and Exeter Dental Hospital.—In response to the Leeds University's appeal for £500,000, the first list of subscriptions includes donations and promises amounting to £115,370. Among the larger donations contributed are £20,000 from Messrs. Joshua Tetley and Son, Ltd., brewers, Leeds: £18,000 from the Clothworkers' Company, London; £10,000 from an anonymous subscriber; £5000 each from Mr. H. J. Bouring, Kirkby Lonsdale; Sir Algernon Frith, Bt., Knaresborough; and Messrs. Reckitt and Sons, Ltd., Hull; £3000 each from Messrs. E. J. Arnold and Sons, printers, Leeds; Messrs. A. W., Sir Ernest, and J. Bain; Colonel T. Walter Harding, Cowbridge; and the Misses E. G. and E. M. Lupton, Leeds; the *Daily Mail*, London, 2000 guineas.—A bazaar at Dudley, Worcestershire, promoted last June to wipe out the debt of £10,000 on the local hospitals, has had a remarkable success, as the net proceeds amounted to considerably over £14,000.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY, Burlington House, Piccadilly, W.

Thursday, Nov. 5th, 4.30 p.m.—*Papers to be Read:* L. Ballif, J. F. Fulton, and E. G. T. Liddell: Observations on Spinal and Decerebrate Knee-jerks with Special Reference to their Inhibition by Single Break-Shocks (communicated by Sir Charles Sherrington, P.R.S.). K. Furusawa: Muscular Exercise, Lactic Acid, and the Supply and Utilisation of Oxygen. Part XIII. The Gaseous Exchanges of Restricted Muscular Exercise in Man (communicated by Prof. A. V. Hill). K. Furusawa: A Spirometer Method of Studying Continuously the Gaseous Metabolism of Man During and After Exercise (communicated by Prof. A. V. Hill). D. T. Harris: The Effect of Light on the Circulation (communicated by Prof. E. H. Starling. *Papers to be Read in Title only:* A. V. Hill: The Surface Tension Theory of Muscular Contraction. J. F. Fulton and E. G. T. Liddell: Electrical Responses of Extensor Muscles during Postural (Myotatic) Contraction (communicated by Sir Charles Sherrington). L. N. Katz: On the Supposed Pluri-segmental Innervation of Muscle Fibres (communicated by Prof. A. V. Hill). L. N. Katz and C. N. H. Long: Lactic Acid in Mammalian Cardiac Muscle. Part I. The Stimulation Maximum (communicated by Prof. A. V. Hill). H. J. G. Hines, L. N. Katz, and C. N. H. Long: Lactic Acid in Mammalian Cardiac Muscle. Part II. The Rigor Mortis Maximum and the Normal Glycogen Content (communicated by Prof. A. V. Hill). Phyllis Kerridge, L. N. Katz, and C. N. H. Long: Lactic Acid in Mammalian Cardiac Muscle. Part III. Changes in Hydrogen-ion Concentration (communicated by Prof. A. V. Hill). W. E. Garner: The Mechanism of Muscular Contraction (communicated by Prof. A. V. Hill). R. W. Riding and E. C. C. Baly: The Occurrence of Helium and Neon in Vacuum Tubes. O. W. Richardson: Structure in the Secondary Hydrogen Spectrum. III. T. R. Merton and J. G. Pilley: On the Excitation of the Band Spectrum of Helium. H. Hartley and J. E. Frazer: The Conductivity of Uni-univalent Salts in Methyl Alcohol at 25° C. (communicated by Prof. J. W. Nicholson). C. S. Beals: The Arc Spectrum of Palladium: its Zeeman Effect and Spectral Type (communicated by Prof. A. Fowler). N. Ahmad: Further Experiments on the Absorption and Scattering of γ Rays (communicated by Sir Ernest Rutherford). R. A. R. Tricker: A Determination of the Variation of the Mass of the Electron with Velocity, using Homogeneous β Rays. Preliminary Results (communicated by Sir Ernest Rutherford). E. H. Boomer: Experiments on the Chemical Activity of Helium (communicated by Sir Ernest Rutherford). R. M. Wilmotte: On the Construction of a Standard High Frequency Inductive Resistance and its Measurement by a Thermal Method (communicated by Sir Joseph Petavel). R. B. Brode: The Absorption Coefficient for Slow Electrons in the Vapours of Mercury, Cadmium and Zinc (communicated by Prof. F. A. Lindemann). P. Kapitza and H. W. B. Skinner: The Zeeman Effect in Strong Magnetic Fields (communicated by Sir Ernest Rutherford). F. R. Weston: The Flame Spectra of Carbon Monoxide and Water Gas. Part II. (communicated by Prof. W. A. Bone). H. S. Hirst and E. K. Rideal: The Thermal Decomposition of Nitrogen Pentoxide at Low Pressures (communicated by Sir William Pope). R. W. Gurney: The Number of Particles in the Beta-Ray Spectra of Radium B and Radium C (communicated by Sir Ernest Rutherford).

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, Nov. 3rd.

ORTHOPÆDICS: at 5.30 P.M. (Cases at 5 P.M.)
Cases:
Mr. R. C. Elmslie: Unintentional Arthroplasty of Hip-joint.
Mr. St. J. D. Buxton: Charcot's Spine.
Other cases will be shown.
Specimen:
Mr. Blundell Bankart: Ovarian Carcinoma of the Scapula.

PATHOLOGY: at 8.30 P.M., at the Imperial Cancer Research Fund Laboratories, 8, Queen-square, W.C.

Wednesday, Nov. 4th.

SURGERY: at 8.30 P.M.
Discussion on
Precancerous States.
Openers:
The President (Sir Lenthal Cheatle), Mr. Sampson Handley, Dr. Sequeira, Mr. Zachary Cope.

Thursday, Nov. 5th.

OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.
Specimens:
Mr. T. G. Stevens:
(1) Fibromyoma of the Uterus weighing 47 lb. 5 oz. Removal.
(2) Large Cystic Tumour of the Liver simulating an Ovarian Cyst.
Short Communication:
Dr. D. W. Roy and Dr. R. Donaldson: A Case of Early Endometrioma of the Fallopian Tube.
Dr. Wilfred Shaw: The Origin of the Lutein Cells of the Corpus Luteum.
Paper:
Mr. Victor Bonney: Myomectomy as the Operation of Election for Uterine Fibroids.

Friday, Nov. 6th

LARYNGOLOGY: at 5 P.M. (Cases at 4 P.M.)
Cases and *Specimens* will be shown by Mr. M. Vlasto, Dr. Dan McKenzie, Sir James Dundas-Grant, Dr. O. Popper, Dr. A. L. Macleod, Mr. Leslie Powell, and others.

ANÆSTHETICS: at 8.30 P.M.
Discussion on
Anæsthetics in Children, to be opened by Dr. Harold Sington.
Other Speakers:
Dr. J. Birt, Mr. Twistington Higgins, and Mr. Pitts.

STUDY OF DISEASE IN CHILDREN: Members of this Section are specially invited to attend the above meeting.

Saturday, Nov. 7th.

OTOLOGY: at 10.30 A.M. (Cases at 9.45 A.M.)
Cases will be shown by Mr. Ibbotson, Mr. Layton, Mr. Just, and others.
Paper:
Mr. A. R. Tweedie: The Otolith Reactions (with demonstration).
A discussion will follow.

ROYAL INSTITUTION, 21, Albemarle-street, W.
Monday, Nov. 2nd.—5 P.M., General Meeting of the Members.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.
Wednesday, Nov. 4th.—8.30 P.M., Sir Thomas H. Holland, F.R.S.: Inaugural Address on the Organisation of Scientific Research throughout the Empire.

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION, 11, Chandos-street, Cavendish-square, W.
Friday, Nov. 6th.—4.45 P.M., Dr. A. I. Simey: The Prophylaxis of the Common Cold and Febrile Catarrhs.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, 1, Pall Mall East, S.W.
Thursday, Nov. 5th.—5 P.M., Dr. E. Bramwell: The Myopathies. (Bradshaw Lecture.)

THE FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.
Monday, Nov. 2nd, to Saturday, Nov. 7th.—Fellowship of Medicine Lecture, Medical Society, 11, Chandos-street. Mon., 5.30 P.M., Dr. J. Campbell McClure The Climatic Treatment of Tuberculosis.—Chelsea Hospital for Women, Arthur-street, S.W. Post-graduate course in Gynæcology, lectures and demonstrations daily, pathology, and operations.—London School of Hygiene and Tropical Medicine, Endsleigh-gardens. Tues. and Thurs., lecture-demonstration by Dr. G. C. Low and Dr. Manson-Bahr.—London Lock Hospital, Dean-street, W. Comprehensive course. Instruction in the Out-patient Department every day and lectures.

UNIVERSITY COLLEGE, London.
Monday, Nov. 2nd.—5 P.M., Mr. R. J. Lythgoe: The Physiology of Hearing and Vision. Seventh lecture.
Wednesday.—5 P.M., Last lecture.

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.
Tuesday, Nov. 3rd.—5 P.M., Dr. Knowsley Sibley: Principles of Treatment. Local.
Thursday, Nov. 5th.—5 P.M., Dr. A. M. H. Gray: Eruptions Due to External Irritants.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.
POST-GRADUATE COURSE: October–November, 1925.
Clinical Lectures and Demonstrations.
Monday, Nov. 2nd.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Headache and its Treatment: Dr. Risien Russell.
Tuesday, Nov. 3rd.—2 P.M., Out-patient Clinic: Dr. Walshe. 3.30 P.M., Peripheral Neuritis: Dr. Grainger Stewart.
Thursday, Nov. 5th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Hemiplegia: Dr. Walshe.
Friday, Nov. 6th.—2 P.M., Out-patient Clinic: Dr. Adie. 3.30 P.M., Electro-therapy in Lesions of Peripheral Nerves: Dr. Bailey.
The Fee for the Course, including Pathology Lectures, is £5 5*s.* For those who hold Perpetual Tickets the fee is £3 3*s.*

Course of Lectures and Demonstrations on the Pathology of the Nervous System.
Thursday, Nov. 5th.—12 noon, Acute Inflammation: Dr. J. G .Greenfield.

Course of Lectures and Demonstrations on the Anatomy and Physiology of the Nervous System.
Monday, Nov. 2nd.—12 noon, The Basal Ganglia: Dr. J. L. Birley.
Dr. H. J. Macbride is giving a Course of Eight Clinical Demonstrations, chiefly on Methods of Examination of the Nervous System, in the wards at 10 A.M. on Tuesdays and Fridays. The fee for this Course is £2 2*s.*
Mr. Armour and Mr. Sargent operate at the Hospital on Tuesdays and Friday mornings at 9 A.M., or at such other times as may be announced.
Any part of the Course may be taken separately. Special arrangements will be made for those unable to take the whole Course.
Fees should be paid to the Secretary of the Hospital at the Office on entering for the Course.
J. G. Greenfield, Dean of Medical School.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
Thursday, Nov. 5th.—3 P.M., Mr. J. Howell Evans: Cases of Affections of the Breast. 4.30 P.M., Mr. W. Ibbotson: Hoarseness, its Causation, Diagnosis, and Treatment.
Daily: In-patient and Out-patient Clinics in General and Special Departments, Operations, &c.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL, Marylebone-road, N.W.
Thursday, Nov. 5th.—5 P.M., Mr. A. W. Bourne: Common Obstetric Difficulties.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.
Tuesday, Nov. 3rd.—4.15 P.M., Dr. D. E. Core: The Oculo-Motor Apparatus from the Physician's Point of View.
Friday, Nov. 6th.—4.15 P.M., Prof. E. D. Telford: The Diagnosis of Chronic Arthritis in Children.

ANCOATS HOSPITAL POST-GRADUATE LECTURES.
Thursday, Nov. 5th.—4.15 P.M., Mr. H. Platt: The Treatment of Common Fractures with Practical Demonstrations.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.
Wednesday, Nov. 4th.—4 P.M., Dr. E. Farquhar Buzzard: The Prevention and Arrest of Nervous Disease.

PEOPLE'S LEAGUE OF HEALTH, Fyvie Hall, Regent-street Polytechnic.
Friday, Nov. 6th.—6 P.M., Prof. H. R. Kenwood: Hygiene.

Appointments.

George, A. W., M.D., C.M. Edin., has been appointed Resident Medical Superintendent, Norwood Sanatorium, Beckenham Park, Kent.

Kirk, Miss F. S., M.B., Ch.B. Glasg., D.P.H., to the combined post of Demonstrator in Pathology in the University of Sheffield, and Assistant Pathologist to the Jessop and Children's Hospitals.

Parry, C. P., M.D., C.M. Edin., to be one of the Medical Referees under the Workmen's Compensation Act, 1906, for Circuit 31, the Districts of the Aberayron, Cardigan, Carmarthen, Llandilo Fawr, &c.

Polson, C. J., M.B., Ch.B. Birm., Demonstrator of Pathology, University of Manchester.

Paddington Green Children's Hospital: Dunstan, C. K., M.B., Ch.M. Sydney, House Physician; Mundell, F. G., M.B., B.S. Durh., House Surgeon.

Certifying Surgeons under the Factory and Workshop Acts: Ling, C. C., L.R.C.P. Lond., M.R.C.S. (Ramsgate); Wilson, G., M.B., C.M. Aberd. (Nairn); Gabb, H.P., L.R.C.P. Lond. M.R.C.S. (Guildford); Moran, L., M.B., B.Ch. N.U.I. (Looe).

Vacancies.

For further information refer to the advertisement columns.

Aberdeen Royal Infirmary.—Asst. S. to Ear, Nose, and Throat Dept.

Bath, Royal Mineral Water Hospital.—R.M.O. At rate of £130.

Birmingham City Hospitals for Infectious Diseases.—Sen. Asst. M.O. £400.

Birmingham General Hospital.—Asst. P.

Birmingham Union, Selly Oak Hospital—Res. Asst. M.O. £300.

Charing Cross Hospital Medical School.—Lectureship in Hygiene.

Chelsea Hospital for Women.—Anæsthetist. £21.

City of London Hospital for Diseases of the Heart, &c., Victoria Park, E.—H.P. at rate of £100.

City of London Maternity Hospital, City-road, E.C.—Obstet. S. Also Asst. Obstet. S.

Coventry and Warwickshire Hospital.—Res. Jun. H.S. £135. Also Res. H.P. £125.

Hospital for Sick Children, Great Ormond-street, W.C.—Med. Reg. and Pathologist. £300.

Infectious Hospitals Service, Metropolitan Asylums Board.—Jun. Asst. M.O. £500.

Manchester, Barnes Convalescent Hospital, Cheadle.—Res. M.O. £250.

Middlesex County Council.—Asst. M.O. £600.

Northampton General Hospital.—Hon. Asst. S.

Oxford, Radcliffe Infirmary and County Hospital.—H.P., H.S., Cas. H.S., and Obstet. H.P. All at rate of £120.

Oxford, Warneford Mental Hospital.—Asst. M.O. £250.

Queen Mary's Hospital for the East End, Stratford, E.—Hon. Asst. S.

Royal Eye Hospital, St. George's Circus. S.E.—Hon. Asst. S.

Royal Free Hospital, Gray's Inn-road, W.C.—H.P., First H.S., Second H.S. and Asst. Cas. O. Obstet. H.S., Gynæcological H.S. Also Asst. for X Ray Dept.

Royal Northern Hospital.—H.S. At rate of £70. Also Two Cas. O.'s. At rate of £90.

St. John's Hospital for Disease of the Skin, 49, Leicester-square, W.C.—Pathologist. £100.

St. Mary's Hospital for Women and Children, Plaistow, E.—Hon. Dental S.

Salford Education Committee.—Asst. Sch. M.O. £600.

Stockport Infirmary.—Third Res. M.O. £175.

Sudan Medical Service.—Three M.O.'s. £E.720.

University of London.—Associate Examiners.

Western Skin Hospital, 44, Hampstead-road, N.W.—Hon. Radiologist.

Westminster Hospital, S.W.—M.O. Two Asst. M.O.'s to X Ray Dept. Also Asst. Path.

Willesden, Park Royal Hospital, Acton Lane.—Second Asst. M.O. £400.

York Maternity Hospital.—H.S. £250.

Births, Marriages, and Deaths.

BIRTHS.

BARLOW.—On Oct. 21st, to Eileen S. P. Barlow, M.B., Ch.B., the wife of A. Malcolm Barlow, M.R.C.S., L.R.C.P.—a daughter.

CARLILL.—On Oct. 24th, at North Gate, Regent's Park, the wife of Hildred Carlill, M.D., of a son.

COATS.—On Oct. 20th, at Glasgow, the wife of Captain D. H. Coats, R.A.M.C., of a daughter.

DOHERTY.—On Oct. 20th, at a nursing home at Croydon, the wife of W. D. Doherty, M.Ch., F.R.C.S., of a daughter.

SOWRY.—On Oct. 22nd, at Newcastle, Staffs, the wife of G. H. Sowry, M.D., M.R.C.P., of a son.

MARRIAGES.

JACKSON—HADLEY.—On Oct. 21st, at St. Luke's Church, Reigate, Lawrence Nelson Jackson, M.B., to Margaret C. N. Hadley, M.B., daughter of Dr. and Mrs. Wilfred Hadley, of Reigate.

SCOTT—HEWETT.—On Oct. 17th, at St. Margaret's Church, Barking, Dr. John Murray Scott, to Valentine, third daughter of R. M. Hewett, J.P., of Roden Lodge, Barking, Essex.

DEATHS.

DUNN.—On Oct. 19th, at Mentone, suddenly, William Edward Nickolls Dunn, M.B. Lond., and Major, R.A.M.C., aged 54.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

BRADFORD'S HOSPITAL APPEAL.—Owing to trade depression, it is announced that Bradford's public appeal for £500,000 towards the erection of a new hospital to take the place of the present Royal Infirmary has been deferred. Shortly before the war a site for the new hospital was obtained and plans were prepared for a new building.

Notes, Comments, and Abstracts.

THE PREVENTION AND ARREST OF RHEUMATIC DISEASE.*

BY MATTHEW BURROW RAY, D.S.O., M.D. EDIN.,
HON. SEC., BRITISH SUBCOMMITTEE, INTERNATIONAL COMMITTEE ON RHEUMATISM.

PUBLIC attention is being increasingly focused on the serious position created by the heavy incidence of rheumatic disease in this country. Its far-reaching effects on industry have been made manifest by the publication of Report No. 23 in the series on public health and medical subjects issued last year by the Ministry of Health, entitled the Incidence of Rheumatic Diseases,[1] where it was shown that practically one-sixth of the entire sick absence in this country from all diseases was due to those classed as "rheumatic," and reports from other countries show a similar state of affairs. We may say that the problem of the incidence of rheumatic diseases is one which is seriously affecting the whole of Northern Europe. A committee on rheumatism has been appointed by the International Society of Medical Hydrology and from it a subcommittee to deal with its incidence in this country, which has for its object the formulation of a plan for concerted action in a campaign against rheumatic disability.

Nomenclature and Classification.

If we were asked for a definition of the precise meaning we are to attach to the term rheumatism or rheumatic disease, we could only say that it is a comprehensive name that is applied in an indiscriminate manner to a group of diseases which differ widely in their causation and manifestation. From a scientific point of view, therefore, the name has little to recommend it, and it has frequently been suggested that it be abolished from medical terminology altogether, or, at any rate, limited to those acute and subacute conditions known as rheumatic fever or acute and subacute rheumatism. On the other hand, it has, by reason of its long-continued use, acquired a certain meaning, and if it is regarded purely as a "clinical concept" and not as a "disease picture," its retention in the present state of our knowledge may be justified. Chronic joint changes and painful affections of the connective tissue have obviously little or no relation to those conditions known as acute and subacute rheumatism where the chief damage falls on the heart, and the arthritic changes are merely transient though doubtless very painful in some instances. Indeed, it is a common clinical observation that in the most severe forms of acute rheumatism the joints may escape altogether. We would say then that rheumatic disease appears to fall naturally into three main groups. We have those acute and subacute conditions which are classified under the heading of rheumatic fever which we should place in the first group. The second group would comprise all those painful and disabling conditions which affect the connective tissue that forms the aponeuroses and sheaths of the muscles and nerves. The third group consists of a medley of joint affections chiefly marked by their progressive nature, chronicity, and crippling effects.

These groups are further subdivided into nine subgroups as follows: Group A. (1) rheumatic fever or acute rheumatism; (2) subacute rheumatism, including rheumatic purpura. Group B. (3) muscular rheumatism, sometimes called chronic rheumatism, includes myalgia, fibrositis, pleurodynia, and torticollis; (4) lumbago; (5) sciatica and brachial neuritis. Group C. (6) rheumatoid arthritis; (7) osteo-arthritis, including malum coxæ senilis and most cases of spondylitis deformans; (8) gout, acute and chronic; (9) chronic joint change unclassifiable.

It must be clearly understood that the above is not a classification of arthritis. The whole question of the classification of the arthritides is a very vexed one.

Rheumatic Fever.

Although rheumatic fever is usually regarded as an infective disease, the causal organism has not yet been definitely identified. The disease is essentially one of temperate and humid climates and is apparently rarely found in the tropics. So far as this country is concerned the Ministry of Health point out in their report that it shows a heavy incidence in Bristol, Nottingham, and Cardiff, and a light incidence in the South-Eastern Division and Cornwall.

It is a hopeful sign that the public is beginning to recognise the devastating effect on the health of the community brought about by the occurrence of rheumatic fever in early life. It must be emphasised that it is essentially a disease of childhood. We know comparatively little about its various modes of onset and also what really constitutes the disease. Too much attention is paid to the joint conditions which, from the point of view of prognosis, are of little moment. Many children have had their lives ruined by the failure to recognise the disease in the absence of joint changes.

---

* Abstract of an address delivered at the Royal Institute of Public Health on Oct. 21st, 1925.

[1] THE LANCET, 1924, i., 451.

Prevention.—The question of the prevention of acute rheumatism really resolves itself into one of early recognition of the condition. In the first place we have to learn to differentiate the type of child likely to be affected therewith. With the routine examination of all school-children there should be no difficulty in setting aside for special consideration in each school those children who exhibit signs of this diathesis. They are usually pale and anæmic and sweat readily, and careful examination will reveal the presence of small subcutaneous nodes, to which Vincent Coates and R. E. Thomas have already drawn attention. The home surroundings of such children should be specially investigated under the headings of elevation, overcrowding, dampness of house or site, amount of sunlight. It has been pretty well established that low-lying sites near rivers are particularly favourable to the incidence of this condition. Where possible, children who show tendencies to rheumatic affections should be removed to more favourable surroundings. I am quite aware that such a scheme would meet with a good deal of opposition on the part of parents, who naturally dislike to have their children sent away. This difficulty can only be overcome by the enlightenment of the public as to the danger of permanent invalidism to which these children are exposed.

In this connexion the importance of a publicity campaign with the object of educating the public in the need for a concerted effort to protect our children from the devastating effects of this disease cannot be too strongly urged. Special hospitals for the treatment of children who have had an attack of rheumatic fever should be established all over the country. These institutions would differ from the ordinary hospital in that the patients would be kept for prolonged periods. While undergoing their rest there is no reason why their education should suffer, so that these institutions would really be "school hospitals." Until a specific remedy for acute rheumatism is discovered, the best we can do is to place the sufferers under the most perfect hygienic surroundings we can devise. In the Hartfield Hospital, which is run on more or less "open air" lines, in Sussex, it is found that even under the worst climatic conditions the children improve rapidly and very few after admission develop fever and rheumatic pains.

Non-Articular Rheumatism.

This term includes muscular rheumatism, sometimes called chronic rheumatism or myalgia, fibrositis, pleurodynia, and torticollis. The Ministry place myalgia of the erector spinæ muscles (lumbago) in a class by itself as being an easily distinguishable clinical entity. The remaining subclass comprises sciatica and brachial neuritis. Now, when we speak of muscular rheumatism we are really referring to an affection of the white fibrous tissue which forms an envelope that sends its prolongations everywhere throughout the body and supplies the muscle sheaths and coverings for the tendons and aponeuroses. It acts as a supporting tissue for the blood, lymph, and nerve-supply of the body generally. It must of necessity, therefore, be intimately concerned with all the biological interchange of fluids which are continually taking place as a result of bodily activity.

Ætiology.—There are several theories as to the causation of these painful affections, but it can be shown that they largely depend on the retention in the plasma of the waste products of metabolism which interfere with the efficient removal of the products of muscular activity. Intestinal toxæmia is a fruitful source and easily explicable. Cold, especially when prolonged, is another very common cause. The incidence of a stiff neck or an attack of lumbago consequent on sitting in a draught, possibly in wet clothes, is a usual experience; heat is necessary for efficient muscular action, and the chilling of large surfaces of the skin along with its contained blood must interfere with its excretory functions. With regard to the bacteriological side of the question, it would be futile to deny that in many instances the removal of some infective foci in cases of fibrositis or muscular rheumatism has been followed by rapid improvement or a complete cure of the condition.

Prevention should obviously comprise such measures as the avoidance of prolonged surface chilling to the body—the adequate warming of work-rooms, the provision of facilities for drying clothing. Attention should be paid to housing conditions, such as dampness, low-lying situations, and the like. As the condition is, so far as I envisage it, dependent in a great measure to metabolic irregularities, due attention should be paid to the diet. A diet excessive in starch is very apt to cause intestinal fermentation, and it has been observed that patients suffering from both this condition and one which affects the joints in a manner to be described later, show a diminished sugar tolerance.

With regard to the *arrest* of the condition, the treatment is both general and local. Dietetic errors should be corrected. Where possible a course of treatment at a selected spa is, in the majority of instances, of the greatest benefit. The daily intestinal flush combined with local measure stimulates metabolism and quickly promotes a cure. Heat and massage are the most important local measures we have at our disposal for the treatment of muscular rheumatism or fibrositis. There are two objects to be kept in view, one to promote a freer lymph circulation and the other to break up the nodules. When possible a radiant heat bath should be given as a prelude to the massage. If such a bath is not available the old-fashioned hot flat-iron over a few layers of flannel is almost if not quite as effective. To promote free circulation the muscles should be kneaded with the palm of the hand the thumb being kept behind. This method is very well adapted for the neck muscles and for those in the spine and lumbar region. For the nodules, each individual one that can be felt should be treated in turn. The ball of the thumb, previously anointed with a little vaseline, should be employed. The movement should be a combination of pressing and rolling against the underlying bone if possible. Under such pressure the nodules will be felt gradually to soften and disappear. Older ones naturally take longer.

Rheumatoid Arthritis—Two Types.

Rheumatoid Arthritis, Osteo-Arthritis, Gout, and Unclassified Joint Conditions.—It is in connexion with the group of joint affections that difficulties in description chiefly arise. The task is not made any easier by the numerous attempts at classification that each observer feels himself called upon to make. Some classifications have an anatomical basis, others are based on supposed ætiological conditions, while others again are founded on a combination of the two, which only makes confusion more confounded.

Rheumatoid arthritis is an unfortunate name for the condition to which it is applied, because it lacks distinctiveness. It moreover labours under the disadvantage of being applied to what in my opinion are two distinct and separate diseases. Anatomically speaking, they have this in common—i.e., that in the early stages of the condition the changes are mainly confined to the structures round the joints, and the name "infective periarthritis" has been suggested in consequence.

The first type of rheumatoid arthritis or infective periarthritis is characterised as follows: It may be seen in an adult male or female of any age. It may commence suddenly in a large joint such as the knee or wrist, or in a smaller such as the metacarpo-phalangeal of the middle or index-finger, which become swollen and inflamed and later on become spindle shaped. There may be considerable constitutional disturbance at the onset of the condition, and it is sometimes difficult to say whether such a case at first is or is not one of subacute rheumatism or subacute rheumatic fever. The subsequent progress of the case will clear up the diagnosis, as in that the joint affections of subacute rheumatic fever rarely if ever tend to become chronic and progressive. On the other hand, in this variety of rheumatoid arthritis much permanent damage may be done. It leaves in its train wasting of muscles, ankylosis of joints, frequently with much distortion. This is the class of case, perhaps above all others, which eventually becomes a burden to the State or dependent on his friends or on charity.

With regard to the *causation* of this condition, the presence of a local focus of infection—the teeth, tonsils, or an inflamed gall-bladder or appendix—should be considered. Another contributory cause which has not received the attention it deserves is that of derangements in the circulation of the skin and periphery generally. It would appear that the importance of the skin as an organ of defence against disease is even now not fully realised. The prolonged application of cold, therefore, to the surface of the body must of necessity have a powerful effect on the functions of the skin as an excretory organ, in that toxic by-products are retained in the circulation and are thus liable to deposition in the joints, or rather round the joints. This is probably the explanation of the influence of climatic conditions on the incidence of this form of rheumatic disease. This particular type is specially prevalent in cold and humid climates. Humidity of the atmosphere alone is not sufficient. It is not nearly so prevalent in districts with a heavy rainfall and a relatively high mean temperature as in localities with a smaller rainfall but a lower mean temperature. The same explanation will apply equally well to conditions of industrial employment where the workers are exposed to a damp, cold atmosphere. It will also account for its heavy incidence in districts with a damp clay subsoil and in houses with an inefficient damp course.

Prevention.—The general lines on which preventive measures should proceed would obviously include the removal of "hearths" of infection, the avoidance as far as possible of prolonged surface chilling, adequate provision for the drying of clothes in factories, the maintenance of an equable temperature in work-rooms. Dietetic conditions deserve more than a passing mention. There is a firmly fixed idea among the lay public that red meat is unsuitable for rheumatic cases, with the consequence that arthritics are apt to overdo the carbohydrate side of their dietary. In view of the fact that most of these people have a lowered sugar tolerance, the diet should consist as far as possible of red meat, fish, fats, green vegetables, and fruit. The vitamin-content of the food is of considerable importance. In this connexion vitamin B is essential in aiding the efficient action of the intestines. A dietary deficient in this particular vitamin is apt to induce flatulent distension and stasis, two conditions specially favourable to the formation of toxins which may eventually find their way to the joints. Among the industrial population the consumption of tinned and bottled foods is much greater that there is any necessity for. If the advantages of freshly prepared wholesome food could be brought home to many people who attempt to subsist on canned meat and vegetables, it would, to say the least of it, be all to the good.

The *treatment* or arrest of this condition, after the search for and removal of any discoverable "hearth," must be largely hydrological. Mineral waters are of great value from their flushing action, whereby intestinal toxins are swept from the system. The aim of bath treatment is to produce in the first instance an active hyperæmia. This may be induced by hot air, steam, or immersion mineral-water baths, such as brine, peat, sulphur, mud, or fango. Manipulative baths, either under water or under a douche directed on the part, are also extensively employed with the greatest success.

The other condition to which the name rheumatoid arthritis is applied occurs mainly in young women and is, perhaps, never seen in the male. We have, therefore, at the outset a distinction which should entirely separate it from the affection we have just described. Cases of this type amount to one-sixth of all those of infective periarthritis. The French regard this disease as a tuberculous manifestation, and other observers ascribe a neurotrophic origin for it. It has a special prevalence among young women who follow an indoor occupation, dressmakers, school teachers, and the like. It commences slowly and insidiously, attacking the smaller joints of the fingers, the metacarpo-phalangeal, or the mid-phalangeal joints. It is symmetrical and centripetal, involving the wrists and ankles after the toes and fingers. The temporo-maxillary joint is frequently affected. There may be associated nervous conditions such as sweating, glazing of the skin, with atrophy of muscle and bone. The removal of a supposed focal infection does not appear to arrest the disease. Sufferers from this condition show all the signs of a profound metabolic upset. They are pale and anæmic, their circulation is feeble, and trophic changes are common. It is a progressive disease. Ankylosis does not always occur, but subluxation and distortion of the finger-joints are extremely common, and the patients are very neurotic.

Every possible measure that can be devised in the way of building up the constitution and increasing the resistance of the patient must be tried. A course of arsenical waters have repeatedly been found to be of great benefit. The patients must be removed from unhygienic surroundings and placed where they will get plenty of fresh air and sunshine. Treatment by the ultra-violet rays has shown encouraging results, but it is perhaps early to speak very definitely on this point.

Osteo-Arthritis.

This condition has not the same climatological and geographical limitations as the others.

Evidences of osteo-arthritis are found in the skeletons of man and even in prehistoric animals all over the world, and are especially well seen among the bones of ancient Egyptians in various museums. Timbrell Fisher points out that in osteo-arthritis we are faced with a borderland between a frankly inflammatory condition and a neoplasm of the joint structure. He further shows that a striking feature which distinguishes the disease from the more acute and probable infective group of conditions known as rheumatoid arthritis is the almost invariable absence of small cell infiltration.

Osteo-arthritis is gradual in its onset, and is more prevalent in the later decades of life. It is as often as not monarticular and one of the larger joints is usually affected, the hip, knee, or shoulder probably most frequently. Although it usually becomes more or less concentrated in one joint, X ray photographs will often demonstrate an earlier condition in some of the other joints. This condition is very frequently associated with arterio-sclerosis and high blood pressure. The sufferers are usually well-nourished and present quite a different appearance to those suffering from infective periarthritis. One can often form a shrewd idea as to the condition by the first look at the patient before proceeding to the examination of the joints.

Ætiology.—Opinions differ as to the precise ætiology of this disease. There are those who say it is due to a low form of septic infection occurring in the intestinal tract or bladder. Personally, I am not inclined to this view. I have seen a certain amount of improvement follow the removal ot an obvious septic focus, but I do not think such focus was a direct cause of the condition. In a great number of cases a history of a strain or injury to the joint, often years previously, can be obtained. The injury in the first place lowers the resistance in the joint and toxins, probably metabolic in origin, find their way to the site of lowered resistance, with the result that the familiar train of symptoms ensues.

Prevention.—The avoidance of metabolic errors, even though a counsel of perfection, would seem to be one of the chief points with regard to the prevention of the condition.

Treatment.—These cases derive great benefit from spa treatment. This is proved by the fact that they return again and again to the spa of their choice. The internal administration of the various aperient waters, saline and sulphur, reduces weight, lowers blood pressure, and corrects faulty metabolism. The local treatment that they undergo improves the condition of the skin and aids in the elimination of toxins. Manipulative douches improve the condition of the muscles round the joints. It is perhaps here that we should utter a word of caution as to the manipulative treatment of the stiff joints. Too vigorous movements and attempts to move fixed joints may do more harm than good. The masseur should confine his attention to the structures round the joint and leave the joint itself alone. Where there is much pain, local applications of steam, hot water, and peat are most comforting.

Acute and chronic gout are included in the Ministry's list of rheumatic disease owing to the difficulty in distinguishing some forms of chronic gout from osteo-arthritis.

Villous arthritis consists, as its name implies, of a chronic villous thickening of the synovial membranes of the larger joints. The knee is perhaps the one most commonly affected. It may be found in the hip and shoulder. It is very common in women about the time of the menopause, and is easily discoverable by palpating the moving joint when a curious soft crepitus will be heard or felt. The thickened synovial membrane can be distinctly felt bulging out from the joint. It is often associated with incipient flat-foot, which in its turn may have been induced by the increase in body-weight.

The treatment is: (1) General: reducing the obesity by suitable mineral waters and attention to the general health. (2) Local: attending to any deformity of the feet by ordering suitable shoes or instep supports. Steam baths, massage, douche, or local douches with manipulation are useful. These are the cases that the cautious exhibition of thyroid extract benefit so markedly. They mostly show slight evidences of hypothyroidism.

Conclusion.

With the exception of the group comprising acute and subacute rheumatism, the employment of baths and water of various kinds occupy a large place in treatment. The majority of these baths are only obtainable at the spas. Those sufferers from rheumatic disease who can afford a three weeks' stay at one or other spa find no difficulty in obtaining them. Insured persons to the number of 370,000 seek advice every year for one or other form of rheumatic disease. The spa hospitals at Bath, Buxton, and Harrogate can only accommodate all told 5000 each year. Not by any means all the patients who seek advice need spa treatment, but a good many more need it than get it; it is obvious, therefore, that increased accommodation is urgently needed at the spas. There is also the urgent need for the provision in London and the larger centres of population of baths and other remedial measures. Many baths and douches of the highest therapeutic value can quite well be given with an ordinary water-supply. Mud or peat can be procured and used as packs. Vapour and hot air baths are quite easy on installation. These proposed remedial institutions should work in liaison with the spas, and would be the "clearing stations" to select cases suitable for spa treatment. A great many cases are sent to spas that are utterly past praying for. It is in the early stages of the malady that physical treatment is most valuable. Lastly, these central institutions would be the headquarters of research. A vast amount of research work is waiting to be done, and up to the present the fringe has hardly been touched. Well-equipped laboratories are already installed at Bath, Buxton, and Harrogate. London and the larger towns are lamentably deficient in such facilities. The expenditure of capital in the provision of facilities for combined research and treatment would well repay the outlay, for the two million pounds at present paid out annually in "benefits" is only a subsistence allowance. Not one penny of it can be regarded as being spent in treatment. There can be no doubt that once the sad situation of this multitude of sufferers from rheumatic diseases was fully realised, means would be quickly forthcoming to relieve their necessities.

PUBLIC HEALTH IN THE UNITED PROVINCES OF AGRA AND OUDH.

THE population of these provinces, according to the 1921 census, was 45,375,787, being less than that of the 1911 census (46,805,913) owing to territorial changes. The vital statistics have been calculated on the 1921 figures, but "the estimated population, worked out up to the half-year ending June, 1923, shows a further increase of 353,737 over the 1911 census figure."

Vital Statistics.

The recorded birth-rate for the Province in 1923 was 36·04 per 1000, as compared with 32·17 in 1922 and 34·88 for the preceding quinquennium. There was marked variation in the different districts, the ratios ranging from 25·47 in Rae Bareli (Lucknow division) and 25·76 in Gonda (Fyzabad division) to 47·27 in Pilibhit, 47·61 in Moradabad, and 49·24 in Bijnor (all in Rohilkhand division). The death-rate was 23·37, as compared with 25·01 in the preceding year, and 45·17 in the quinquennium, the ratios varying from 12·78 in Gonda district (Fyzabad division) and 14·12 in Rae Bareli (Lucknow), to 35·37 in Jhansi and 38·59 in Hamizpur (both in Jhansi division). It is stated (p. 3) that 13,106 births were returned in "notified areas," also that 9793 deaths occurred in these "areas"; but it is not explained what constitutes a notified area, or in what way they differ from the official "districts." The infantile mortality for the Province was 169·37 per 1000 births, a further reduction on 183·8 in 1922, 236·5 in 1921, and 232·3, the decennial average (1911–20); in the urban areas the ratio was 263·91, and in the rural tracts 160·77, as compared with 254·83 and 177·33 in the preceding year. The general mortality in the rural tracts was 22·48, and in urban areas 35·86, as compared with 24·45 and 32·93 in 1922, and 44·86 and 49·07 respectively for the preceding quinquennium.

Epidemic Disease.

Cholera caused 2591 deaths, giving a ratio of 0·06 per 1000, as compared with 0·05 in 1922 and 1·56 for the quinquennium; only five deaths from this cause were registered in the four districts composing Jhansi division (including towns and rural areas), with a total population of 2,065,297, too small a number to yield a ratio of 0·01 per 1000; the highest mortality ratios occurred in Ballia district of Benares division (0·62 per 1000); Naini Tal (0·43), and Aligarh (0·32). For the Provinces as a whole the cholera mortality in rural areas was 0·05, and for the towns 0·17 per 1000; in the former the highest ratios were 0·56 per 1000 in Ballia and 0·45 in Naini Tal; and for the latter 5·40 in Firozabad (Agra district) and 3·40 in Ballia. There was a considerable increase in the small-pox mortality, 747 deaths, as compared with 242 in the previous year (stated as 0·02 per 1000 and 0·01 respectively), but still much below the quinquennial average (0·09); seven districts were entirely free from the disease. In the towns the death-rate was 0·16, and in the rural tracts 0·01; Allahabad district suffered most, with 228 deaths (0·16 per 1000), 174 occurring in children under 10 years of age. Plague also showed a considerable increase, 74,187 deaths, giving a mortality of 1·63 per 1000, against 0·51 in the preceding year, and 1·13 for the quinquennium. Kumaon division (Naini Tal, Almora and Garhwal districts) was entirely free, also ten other districts in various parts of the Province; in Azamgarh district of Gorakhpur division there were 21,227 plague deaths (13·89 per 1000), of which 20,720 occurred in the four months, January to April inclusive. "The attitude of the people towards inoculation was on the whole satisfactory. They realised its value as a preventive measure, but did not volunteer until the disease was actually raging in their villages." The total inoculations numbered 62,615; particulars are furnished as to 5412 persons inoculated, compared with 105,824 not so treated in several districts of the Province; of the latter number 1497 died in the selected areas examined; while of the 5412 inoculated only 4 died. Evacuation was carried out in most districts on the appearance of the disease without any opposition.

Dispensaries and District Boards.

Unfortunately the travelling dispensaries have been reduced from 112 to 45, apparently for financial reasons. Six district boards, Almora, Bulandshahr, Kheri, Gonda, Bahraich, and Gorakhpur have, however, resolved to support them by contributing Rs.1000 per dispensary, the rest of the cost being provided by the Government. During the period under report 1,411,775 patients were treated, and 23,309 operations were performed at these dispensaries throughout the Province. "It is hoped that the experience of one year without them will induce the boards to reconstitute them next year." The district health scheme experimentally introduced in the districts of Gorakhpur and Basti in 1922 was extended to Azamgarh in 1923; instruction was given and hygiene propaganda carried on by lantern demonstrations, lectures to teachers, and articles in the local papers, with good results; owing to financial stringency the extension has been retarded, but it is hoped that it will be resumed as funds permit. "As many as ten municipal boards have not yet appointed medical officers of health on the ground of paucity of funds. It is essential to the welfare of the whole community that towns as large as these should have a properly organised health service. In other civilised countries local bodies of this size, and even of much smaller size are bound by law to employ M.O.H. and sanitary inspectors in adequate numbers." It is time for the United Provinces "to fall into line with other countries in this respect." Moreover, preventive medicine pays, as has been proved over and over again.

PRIMITIVE MORALS.

Mr. B. Malinowski, D.Sc., reader in social anthropology at the University of London, in an address on the Contributions of Anthropology to Social Hygiene, delivered recently at King's College, London, under the auspices of the British Social Hygiene Council, reopened some of the most debatable questions of primitive sexual sociology. On the whole supporting the views of Darwin and Westermarck that monogamous marriage and family existed from the beginning of humanity, the lecturer pointed out that while problems of origins and development were of a merely antiquarian interest, the study of cultural function and aim was of practical importance.

Dr. Malinowski proceeded to show by an extensive examination of anthropological evidence, as well as drawing upon his own researches among Melanesian and Papuan tribes, that propagation, training of the young, as well as the satisfaction of full sexual love, were always fulfilled within the family and the individual marriage. Licence occurred in a number of savage tribes, though by no means in all. It was found either in the form of prenuptial freedom, when it played an important part in effecting the selection of a proper mate by the method of trial and error. It acted also as a safety-valve by which the unruly passions of youth are allowed to find a natural vent. Marriage and the family were never really obliterated or overridden by it. Dr. Malinowski analysed from the same point of view the occasional outbreaks of customary licence in orgiastic feasts, in magical or religious ceremonies, in seasonal relaxations of sexual restraint, explaining their occurrence by their cultural utility at a low level of development. Anthropology would advocate early marriages, equal rights for man and woman, a wise reconsideration of the divorce laws, and an equal moral measure for both sexes. Prostitution, with its concomitants of crime, degradation, disease, and disgenics appeared to the anthropologist as the greatest evil of modern culture. Prostitution placed us morally below the savage. The real problem was how to combine a full life for man and woman with a high moral standard. Good family life and a happy marriage could not be divorced from one another. They could not be achieved by a mere propaganda of continence, but rather by the ideal of an intimate association between the satisfaction of instinct on the one hand and the full expression of love and affection on the other. Physical intimacy without spiritual passion was degrading, while mere mortification of the flesh was in most human beings unnecessary.

EFFICIENCY OF MERCURY-VAPOUR LAMPS.

WE have received from Dr. Frederick W. Alexander, medical officer of health for the Borough of Poplar, a special report issued by him on methods of gauging the intensity of ultra-violet rays from artificial sunlight lamps. The booklet is entitled Practical Artificial Light Treatment, and may be obtained from the Public Health Offices, Bow-road, E. 3. Dr. Alexander says that as the ultra-violet radiations from quartz mercury-vapour lamps begin to fall off from the first day they are brought into use, it is most desirable to have a simple means of measuring their efficiency. Brilliancy is not a reliable guide. After referring to the erythema-dosimeter and the acetone methylene-blue gauge and the views of Dr. A. Eidinow and Dr. Leonard Hill (THE LANCET, 1925, ii., 317), he describes a simple apparatus for daily use which depends on the production of fluorescence on a uranium screen by ultra-violet rays which have passed through a Chance filter. He also records results of exposing photographic printing-paper to the rays of a standard lamp when different filtering media are employed. The results obtained with a lamp to be tested may be compared with the standard.

Messrs. Bengue and Co., manufacturing chemists, have changed their address to 24, Fitzroy-street, London, W. 1.

Mr. F. C. Goodenough, chairman of Barclay's Bank, last week unveiled a brass tablet over the bed in the Burdett Ward of Westminster Hospital, which has been endowed with the proceeds of a concert given last April at the Albert Hall by the male voice choir of the bank.

An Address
ON THE
MANAGEMENT OF HEAD INJURIES.

Delivered before the Warwick and Leamington Medical Society on Oct. 31st, 1925,

BY WILFRED TROTTER, M.S. LOND., F.R.C.S. ENG.,
SURGEON, UNIVERSITY COLLEGE HOSPITAL.

WHEN one deals with any part of the surgery of head injuries it is natural to approach the subject by the way of theory. This is because there is no department in which what we know of practice is more closely and clearly related to what we know of principle, and where the management of actual cases proceeds more directly from pathological understanding. Little as we may and do know of the ultimate physiology of the brain, in so far as the relatively simple processes set going by mechanical injury are concerned, we can already say in general terms and with some precision how injuries are produced, what injuries are likely to occur, and what effects on function they cause; we can see in the majority of cases the meaning of symptoms as they arise; and we can direct such treatment as is possible by reason instead of having to depend on clinical intuition to the extent that is necessary elsewhere. It would, therefore, be wholly logical to begin what I have to say by a general statement of theory from which the necessary practical applications could easily be made. It must be admitted, however, that the theoretical route is a roundabout one, and one which would take us over ground that nowadays, and especially on this occasion, may be assumed to be in great part, if not wholly, familiar to us all. I propose, therefore, to take for granted as common knowledge the established facts concerning the special features of the cerebral circulation, the relation of circulatory disturbance to symptom production, the mere mechanics of cranial and cerebral injury, and the general body of fundamentals established by experiment and inference from it. We shall thus be able to direct our attention especially to matters of treatment and to deal with them in a severely practical way.

THE RELATION OF CEREBRAL SYMPTOMS TO CEREBRAL LESIONS.

It is a very old custom to describe the lesions that may be met with in cases of head injury as (*a*) intracranial hæmorrhage, (*b*) cerebral laceration, and (*c*) cerebral contusion. In clinical work the attempt to distinguish between the last two is of little or no value, and the clinician need concern himself only with the two broadly distinguishable types of hæmorrhage on the one hand, and lesions of the contusion-laceration type on the other. Now it is well known that the brain is peculiar in showing more clearly than most other organs a gradation of symptoms according to the *intensity* of the lesion that causes them. This series of symptoms of graduated severity has long been roughly divided into two classes, the more severe being called "paralytic," the less severe "irritative." The term irritative as applied to the symptoms called forth by the less intense lesions is, for reasons we need not now discuss, unsatisfactory in theory and misleading in practice; it might very well be replaced by the term "sub-paralytic," which has the advantage of being without fallacious pathological implications. Symptoms of paralytic type correspond with maximal interference with the circulation in the affected part, that is anæmia, while symptoms of sub-paralytic type correspond with a less intense circulatory disturbance, that is venous congestion or stasis. In traumatic cases the abnormal pressure on a given part of the brain, necessary to produce anæmia in it, can in general be produced only by grossly extravasated blood; on the other hand, the pressure on a given region necessary to produce venous congestion can be readily produced by the swelling of contusion. Thus we have two pathologico-clinical sequences fundamental in dealing with head injuries—namely, hæmorrhage, anæmia, paralytic symptoms; and laceration-contusion, venous congestion, sub-paralytic symptoms.

For the uses of practice, then, we must learn to regard paralytic symptoms as conclusive evidence of hæmorrhage; such symptoms will tell us, moreover, not only of the presence of hæmorrhage but also of its situation. It must be admitted, however, that definite local hæmorrhage is a comparatively rare event even among the graver cases of head injury. It is obvious, in fact, that the essential damage always tends to be in the nature of contusion-laceration, while hæmorrhage is an occasional complication due to the incidental tearing of a vessel. Thus, even in a case where hæmorrhage can be recognised and dealt with, the surgeon must always recognise that behind the condition he has been fortunate enough to be able to treat, there probably exists more or less severe and widespread laceration-contusion which may yet deprive him of ultimate success. When we speak of the paralytic symptom as characteristic of hæmorrhage we must bear in mind, of course, that all hæmorrhages produce also sub-paralytic symptoms even more constantly and on a wider scale than paralytic symptoms; the latter owe their extreme importance in diagnosis, then, to being the sure index of a pressure on the affected part of the brain greater than can be produced by the swelling of a mere contusion. Conditions of the contusion-laceration type make up the great body of head injuries as we meet them in practice, and, in consequence, the symptoms we most commonly observe are of the corresponding sub-paralytic kind. Among such symptoms may be irritability, restlessness, delirium, drowsiness, headache, giddiness, vomiting, rigidity, twitching, convulsions, alterations of reflexes, temperature, pulse, and respiration. In occasional cases there will be superadded to the symptoms of this group one or more of the true paralytic variety, indicating that the corresponding region is more profoundly affected and is the seat of hæmorrhage. Among such symptoms may be coma, monoplegia, hemiplegia, aphasia, hemianopia, dilated fixed pupil, loss of superficial abdominal reflex, extensor plantar reflex.

THERAPEUTIC GROUPING OF CASES.

It is plainly impossible to make any complete and logical clinical classification of the almost infinitely various material offered by head injuries. Nevertheless there is possible a certain rough grouping, according to the necessities of treatment, which is useful in description and of some practical value if its distinctions are not too rigidly enforced. We may recognise then the following main therapeutic groups: (*a*) Intracranial hæmorrhage, usually, of course, superimposed on more or less contusion-laceration. This group, relatively small in numbers, owes its great importance to the lesion being usually progressive, and, as such, necessarily fatal unless surgical treatment is applied. Exact diagnosis and adequately prompt operation are therefore urgently called for. (*b*) Cases of severe contusion-laceration without recognisable hæmorrhage. These make up the great bulk of clinical material met with in civil practice. As they display no focal symptoms, these cases are often regarded as not calling for operative treatment. Many are rapidly fatal; in those where recovery occurs there is often a long illness, a longer convalescence, and a residue of disabling sequels. The group is important because of its size, the frequency of incomplete recovery, and because operative treatment in judiciously chosen cases is of value. (*c*) Cases of mild contusion-laceration. These owe their importance to the frequency with which they still pass unrecognised because of the absence of grave initial symptoms, to the disabling nature of the symptoms that develop, and to the fact that treatment (often without operation) is effective. (*d*) Local brain injury with external wound, including gunshot wounds and all kinds of punctured or depressed compound fractures of the skull. This class is included merely that we may recognise its importance in passing. The kind of treatment needed in these cases is now so generally understood that discussion of it is superfluous. It is now necessary to deal in some detail with the first three groups defined above.

INTRACRANIAL HÆMORRHAGE.

The classical picture of an intracranial hæmorrhage over one cerebral hemisphere is familiar to us all. There has been a severe accident, concussion, a more or less complete return to consciousness, then drowsiness deepening to coma, hemiplegic signs, a dilated fixed pupil on the side of the hæmorrhage, slow full pulse, slow stertorous respiration, and a rising blood pressure. It is still perhaps necessary to point out that this picture, often regarded as characteristic of hæmorrhage, is that of a far advanced, indeed, nearly terminal, stage. The state of the pupil indicates that pressure enough to cause paralysis has already reached the mid-brain; the pulse and respiration show that sub-paralytic changes have actually reached the medulla. It should, of course, be our object to make the diagnosis in cases of this class long before so advanced and dangerous a state is reached. As has already been pointed out, the appearance of one definite unilateral paralytic symptom should be enough to indicate the presence and approximate site of the hæmorrhage.

Aberrant Types.—While traumatic intracranial hæmorrhage is usually a rapidly progressive condition becoming manifest within a few hours of the accident, and proving fatal if untreated within a few days, much milder forms, both as to intensity and duration, are occasionally met with. In some of these the condition is scarcely to be distinguished pathologically and clinically from a superficial contusion. A comparatively common type is that in which after a week or ten days of rather generalised "irritative" symptoms the development of Jacksonian fits points to a focal lesion of the Rolandic area. Another well-defined type is the *chronic subdural hæmorrhage*, in which, after an accident (often apparently trivial), there is a prodromal period of many weeks with minor symptoms (headache, slight mental changes) followed by the onset of coma. This coma is apt to show remarkable and characteristic intermissions, and the alternating mental states may merge into one resembling advanced dementia. The lesion found is known as "pachymeningitis hæmorrhagica interna," and is an encysted traumatic hæmorrhage. I shall not attempt to remind you of the very familiar details of an operation for intracranial hæmorrhage, but shall venture to make a few remarks on two matters rather of principle than technique.

Multiple Hæmorrhages.—As a rule an intracranial hæmorrhage is single. Exceptions are, however, not very rare; extradural and intradural hæmorrhage may occur on the same side, and bilateral hæmorrhages are not uncommon. If therefore after the evacuation of an extradural hæmatoma the dura is found to be very tense, it should always be incised forthwith as a precaution. Again, if after the apparently successful evacuation of a hæmorrhage on one side symptoms of abnormal intracranial tension persist unduly, the possibility of a hæmorrhage on the other side must very seriously be considered. In the case of chronic subdural hæmorrhage the lesion is far from uncommon on both sides. These cases are of especial importance, since if both hæmorrhages are not evacuated at the same operation the patient is very unlikely to survive.

The Urgency of Operations.—In dealing with head injuries it is of great value to cultivate a sense of the urgency of any necessary operation that shall be both adequate and reasonable. While guarding against the terrible mistake of undue delay we must be on our guard against being led into untimely action by an atmosphere of false emergency. Rapidly extending lesions, capable of producing widespread paralytic symptoms within a few hours, are invariably fatal and not to be helped by surgery; cases capable of recovery have a margin of safety of more than a few hours, and should have the benefit of a careful diagnosis and deliberately designed operation. It may, indeed, even be doubted whether many lives have been saved by operations much within 24 hours of the accident. In grave cases of head injury there is almost always some contusion of the medulla and pons; it seriously increases the danger of the condition, and the knowledge of its probable presence is a strong reason against any but quite indispensable operations.

SEVERE CONTUSION-LACERATION WITHOUT OBVIOUS HÆMORRHAGE.

As we have already said, this is perhaps the commonest clinical picture presented by cases of severe head injury. From the reaction stage of concussion the patient passes into the condition more or less covered by the old clinical term "cerebral irritation." Some affection of consciousness is the most constant feature. The patient is usually drowsy and inert, but hypersensitive and irritable to stimulation by day and restless or even delirious by night. Sometimes the inertia is replaced by delirium and maniacal excitement that may last for weeks. The reflexes may become generally brisk after the effects of concussion have passed off; there may be rigidity and twitching of the limbs. The pulse and respiration are apt to indicate bruising of the medulla by being persistently slow, and there may be periodic phenomena of an incomplete type. Consciousness is scarcely ever actually lost, and the patient can usually be roused to give quite complicated responses, though after recovery there is little or no memory of this period.

A considerable number of patients succumb, usually to increasing bulbar involvement and a terminal pneumonia. Many recover slowly even after weeks of partial unconsciousness. The patients who recover spontaneously are particularly likely to show slight mental changes, epilepsy, or—most commonly of all—persistent severe headaches. The condition here is an extensive contusion of the brain with secondary œdema. Since the brain is rigidly encapsuled by the skull the state of affairs is different in two important respects from that which obtains in any other organ similarly bruised—(*a*) free swelling is not possible, and thus the extravasated blood of the contused tissues and the œdema exercise a certain pressure on the vessels and embarrass the venous return, hence follow venous congestion and sub-paralytic symptoms; (*b*) since the circulation is persistently embarrassed the absorption of extravasated material is very greatly delayed and is apt to be incomplete even for years; the persistent headache which is an evidence of abnormally high intracranial tension is proof of this.

Treatment.

Although many patients ultimately recover, many are seriously ill for long periods, and a large number suffer from disabling sequelæ. Since the inability of the brain to undergo adequate compensatory swelling is the cause of the symptoms, the rational treatment is obviously to do a decompressive operation in order to allow room for such swelling to occur. Experience confirms this view, and the only points of any difficulty are the determination of the cases in which no satisfactory spontaneous recovery can be expected, and the choice of the best time to intervene. Surgical treatment should be advised when at the end of the first week serious mental changes are present (profound drowsiness and inertia, delirium, or mania) and seem to be fairly stationary. In a few very serious cases operation may be called for at an earlier date, but generally the choice of a time is not a matter of great urgency, though of course once it has been decided that intervention is necessary there is no object in delay.

The operation to be done is the making of a fair-sized decompressive opening low down in the right temporal fossa. It is sometimes necessary to make a bilateral opening in order to give adequate relief; in such cases there are probably hæmorrhages that have escaped diagnosis.

MILD CONTUSION-LACERATION.

We now come to what is in some ways the most important part of our subject. The grosser and graver kinds of head injury have long attracted the attention and interest of surgeons; those which we are now about to consider have been comparatively little noticed and until recently not very thoroughly understood. Nevertheless they are met with commonly in practice and are the cause of persistent and distressing symptoms. I refer to the slight or moderate grades of cerebral contusion that are often left by accidents which seem at the time to have produced no serious effect. The symptoms corresponding with such relatively minor cerebral injuries often appear clinically in the form of sequelæ to an accident that had been regarded as unimportant. They rarely have any focal characters, but are manifestations of a disturbed intracranial tension; thus it comes about that their cardinal feature is headache, though this may be accompanied by other less conspicuous elements such as giddiness, slight changes of disposition, and minor mental and physical disabilities. So clear, however, is the primacy of headache among the clinical phenomena that one refers habitually to the cases under the term "contusion headache."

Contusion Headache.—The condition usually declares itself within a few weeks of the accident; if the patient has been laid up the onset of headache often follows the resumption of active life; sometimes, and especially if there has been no period of rest, headache comes on from the first and increases in severity. In well-marked cases the headache occurs in attacks often many hours in duration. The attacks are brought on by excitement, undue exertion of mind or body, and fatigue. Between attacks the patient may feel perfectly well and be capable of leading an active life. Quite commonly, however, in the intervals there is some evidence that the intracranial tension is disturbed; abrupt raising of the venous pressure, as by coughing, straining, or stooping, may cause a transient discomfort, swimminess, or even pain in the head. The headache may be of extreme severity, and is of a throbbing, bursting character. It makes the patient intolerant of movement, effort, or interference, and he is apt to become irritable and sometimes even dangerously enraged if he is not left to himself. The headache is usually relieved by rest in bed in quiet and darkness, and the attack often ends if the patient can get prolonged sleep.

Such symptoms are met with in all grades of severity. The most characteristic features are the throbbing quality of the headache, its paroxysmal character, and the tendency of the attacks to follow some cause recognised by the patient. Contusion headache of greater or less severity is very common, and as it is an extremely distressing and disabling complaint the diagnosis is of great importance. I do not propose to discuss the problem of diagnosis in detail, but shall limit myself to certain general and perhaps rather dogmatically phrased statements. The majority of cases are well marked and unmistakable, a few cases are very difficult, and will cause doubts as to a neurosis or mental disease.

It is a fallacy to suppose that neuroses are particularly common as sequels of head injury, and there can be no doubt that many symptoms have in the past been regarded as neurotic which are, in reality, due to minor injuries of the brain, producing persistent disturbances of intracranial tension. A complete absence of the classical signs of focal cerebral injury is usual in cases of contusion headache, and in no way conflicts with the organic origin of the symptoms.

Treatment.

When the diagnosis is complete, treatment of contusion headache can be undertaken with every reasonable confidence of a satisfactory result. It should be entered upon under the guidance of a very clear conception of the pathological condition that is to be contended with. The brain has been bruised, and by a mechanism that has already been mentioned resolution is rendered difficult and prolonged. Meanwhile the swollen part encroaches upon the strictly limited space available for the brain and its circulatory movements. The result is more or less interference with the venous side of the cerebral circulation, and a tendency for the intracranial tension to be maintained at a slightly raised level. This state of affairs, while it may of itself cause no symptoms so long as the patient is at rest, renders intracranial conditions unduly sensitive to disturbance. If as the result of active exercise there is an increased arterial inflow, the restricted venous outflow at once reveals itself by causing a rapid rise in the intracranial tension. Similarly, if as the result of the patient stooping or straining the venous pressure in the jugulars is raised, this tells back at once on the already restricted venous outflow from the skull and again the pressure rises. It is disturbances on the venous side which are by far the most effective in adding to the already raised intracranial pressure. Only when the arterial circulation is in its most placid state, and the venous outflow at its freest, is it possible in some degree to prevent the intracranial pressure from rising to the point of producing symptoms. Thus it is that rest in bed is the foundation of the treatment of cerebral contusion. It has long been known and insisted on that prolonged rest after head injuries is the best and an indispensable prophylactic against the development of sequelæ. The theory of cerebral contusion confirms this very old clinical doctrine in the strongest possible way.

Even when contusion headache is definitely established, rest in bed is essential to treatment and may in itself be effective. Its purpose is to prevent the attacks and to maintain conditions favourable to resolution of the bruise in the brain. A period of three or four weeks in bed may be necessary in severe cases.

Another important line of treatment by which the abnormal intracranial tension can be influenced acts through the cerebro-spinal fluid. As in other conditions accompanied by œdema of the brain, there is in cases of cerebral contusion a certain accumulation of cerebro-spinal fluid which tends to contribute to the disturbance of the intracranial tension. There are two ways in which this excess can be influenced: (*a*) by lumbar puncture, (*b*) by administering hypertonic saline solutions. Lumbar puncture is most valuable in its place, but, unfortunately, it cannot be repeated without limit. It has its chief value as an emergency measure in severe attacks, but there is no doubt that its effect in giving relief is often more prolonged than might be expected. Hypertonic solutions of magnesium sulphate administered by preference in the form of an enema of 3 oz. of the salt in 6 fl. oz. of normal saline daily, or even twice daily, is said to be capable of producing very obvious relief of intracranial pressure symptoms. Manifestly its use cannot be carried on indefinitely, but it may well be tried for the relief of severe attacks. Another method of exercising a steadily favourable effect on the intracranial condition, and so encouraging resolution of the contused part, is a very simple device which I have found of surprising value in the relief of headache due to moderate increases of intracranial tension. This is to make use of the influence of posture in favouring the venous outflow from the skull. It is sometimes forgotten how considerably the recumbent position raises the pressure in the jugular veins and thus checks the venous current from the brain. This is well shown in a patient with an opening in the skull. In the sitting position—supposing the intracranial pressure to be normal—

the scalp sinks deeply into the cranial opening; lying down the depression is filled up to the level of the surrounding skull because the intracranial pressure closely follows that of the veins and varies strictly with the jugular pressure. It is probably for this reason that so many headaches of intracranial origin—including those of cerebral tumour and even migraine—begin in the morning, so that the patient wakes to the knowledge that he is going to have an attack. It is usually an easy matter to train a patient to sleep propped up in bed, and in my experience the acquiring of this simple accomplishment has frequently been followed by an astonishing diminution in the frequency and severity of headaches.

We have thus a series of relatively simple measures of proved value in dealing with contusion headache. Two I should regard as indispensable and for prolonged use—rest in bed and a rigid enforcement of the propped up position; two should perhaps be chiefly reserved for occasional use and the relief of definite attacks—the administration of hypertonic salines and lumbar puncture.

If thorough treatment by these means for a period of a month or so has proved ineffective, the making of a small decompressive opening low down in the right temporal fossa should be advised. If the contusion headache has followed a local injury of the skull, as was so often seen in the wounds of war, the opening should be made at the injured spot. That typical contusion headaches will be arrested by an adequate decompression is one of the most trustworthy generalisations in surgery.

The largeness of the subject has, of necessity, made our exposition of it both bare and dry, and has prevented the distribution of emphasis on its various parts as one would have wished. In conclusion, therefore, I may perhaps be allowed once more to call attention to the practical value and to the interest to be obtained from following cases of head injury in the light of physiological and pathological principle; to the great frequency and importance of the minor injuries to which the brain is subject; and to the value in them of non-operative and, so to say, physiological methods of treatment.

Cameron Lectures

Delivered at the University of Edinburgh on Oct. 19th, Oct. 20th, and Oct. 22nd, 1925,

BY HARVEY CUSHING, C.B., F.R.C.S. ENG.,
PROFESSOR OF SURGERY IN HARVARD UNIVERSITY.

LECTURE III.[*]—INTRACRANIAL TUMOURS AND THE SURGEON.

> "In einem gewissen Gegensatze steht die Operation der Hirnabscesse zu der der Hirngeschwülste. Für die erstere leistet die Diagnose noch zu wenig, die chirurgische Technik aber genug, für die letztere hat umgekehrt die Diagnose schon so viel gegeben, dass Nothnagel z. B. sie für eine verhältnissmässig leichte erklärt, unsere Technik aber, soweit sie sich auf eine ausreichende Umschneidung, Blutstillung und Vermeidung des gefährlichen Hirnödems bezieht, ist durchaus noch im Rückstande. Vielleicht gelingt es, sie zu bessern und zu vervollkommnen."—*Ernst von Bergmann, 1889.*

NEURO-SURGERY: OLD AND NEW.

IT has been said that three stages—optimism, pessimism, and adaptation—must invariably be passed before any revolutionising principles of surgery can become firmly established. After the introduction of surgical anæsthesia, in which Edinburgh had a hand in the person of James Young Simpson, under whose spell Andrew Cameron must have sat, and after the still more important discovery of surgical cleanliness, the outgrowth of Lister's work which Cameron did not live to see, there was a widespread feeling that the chief obstacles to operations on any part of the body had been overcome. This in a measure was true; but when the surgeon came to attack such non-traumatic lesions within the body cavities as the physician was encouraged to surrender to him, difficulties unthought-of were encountered. It was necessary by slow and devious steps to devise a special technique to overcome these difficulties before the stage of pessimism on the part of the profession as a whole could be overcome.

The first successes were in the lower abdomen, and operative gynæcology, in which another Scotsman, Lawson Tait, had no small part, came into being. Since then the surgeon has been slowly working his way from the lower to the upper abdomen where the liver and gall-bladder, the stomach and pylorus, the kidney and spleen, have, in turn, delayed him. Perfected methods and a novel technique had to be devised before he ventured above the diaphragm into the chest for purposes other than to drain suppurating cavities; and he is now, last of all, coming to feel very much at home in the cranial chamber. But this is so recent a happening that many of us have vivid recollections of the wave of discouragement and pessimism which came on the heels of the generally unsuccessful operations for brain tumours undertaken during the last two decades of the century just gone.

There were some neurologists, among them that Nestor of your local profession, Byrom Bramwell, who, insisting even at that time (1888) that intracranial tumours were common, remarked that the soft brain tissue would seem to be "as fine a forcing and feeding ground for new growths as Koch's nutrient jelly is for micrococci and allied organisms"; and it was stated by Bruns, I believe, not long after, that for a physician to assert he had never encountered a brain tumour in his wards or practice was equivalent to an admission that it had passed under his eyes undiagnosed. But these were voices in the wilderness, unheeded; and in the days before the Wassermann reaction every obscure intracranial lesion was regarded as a potential case of cerebral syphilis. This, at least, was the more probable diagnosis, and, at any rate, something might be done for it therapeutically. Better so than to run the risks of a surgical exploration, with its almost inevitable sequence of a broken-down scalp wound, a fungus cerebri, a cerebro-spinal fluid leak and ultimate fatality, should the condition actually be due to tumour. Such was the lamentable outcome of that first historic operation for a clinically localisable tumour, which Hughes Bennett had the courage to advocate, and which, on Nov. 25th, 1884, his colleague, Rickman J. Godlee, performed.

The young neuro-surgeon of the present day, who only gathers from hearsay or from pictures in his text-books what the horrors of a fungus cerebri used to be, can have no conception of the calamities which commonly followed the intracranial operations for tumour as they were done 30 years ago—unless he looks about him in clinics where old-time methods are still practised by general surgeons blind to what has been going on about them in the development of a specialised technique for these complicated procedures.

Among many others in Great Britain who were pioneers in this work we may salute two outstanding figures: Sir William Macewen, whose major contribution was on the subject of the intracranial infections, now the smallest part of our work; and Sir Victor Horsley, whose troubles are for all to read in the contemporary pages of the British medical weeklies. He was outspoken in ascribing them, right or wrong, to the reluctance of his medical colleagues to surrender their tumour cases, except as a last resort, when it was too late for surgery to accomplish much of anything. But even the echoes of a dispute as to how long a patient suspected of tumour should undergo a course of mercurial treatment before the surgeon was called in have long since died away[1]; and looking back on all this from our present standpoint, one hardly knows which of the two parties needed the more sympathy—doubtless a third party, the patient, most of all. . . .

---

[*] Lectures I. and II. were published in THE LANCET of Oct. 24th and 31st respectively. They are slightly abridged for issue in our columns, and will be published shortly as a small volume, dedicated to a group of young collaborators.—ED. L.

In the course of a sojourn in the Hallerianum in Berne, spoken of in my first lecture, I had learned many things about states of intracranial pressure which were subsequently of more value to me than the acute tension phenomena which were made the chief subject of my reports. They were things, I am sure, long known to others, though it was new to me: that the sinuses are not rigid, but easily collapsed; that respiratory cessation long precedes cardiac failure; that the falx may be markedly distorted by pressure against one hemisphere; that the brain can be widely dislocated without damage if there are contralateral openings; that pressure is not equally distributed throughout the cranial chamber; that choked disc and exophthalmos can be produced by intracranial tension, and so on.

Some degree of familiarity with these matters proved invaluable in my early intracranial operations, and I cannot too strongly emphasise the desirability of anyone proposing to engage in the field of neurosurgery getting his first experience with operations on the central nervous system in an experimental laboratory, particularly should it be one where the ritual of surgical asepsis is observed. I had the further good fortune at the end of this period to pass some months with Prof. Sherrington at the time when he was re-mapping the motor cortex of the higher anthropoids, and as I was permitted to assist at some of these historic operations I became familiar with his methods of unipolar cortical stimulation, which subsequently stood me in great stead.

Armed with these experiences and with a practical, home-made hæmodynometer—an instrument the model of which I had seen in use during a visit to Riva-Rocci's clinic in Pavia, and which promised to enable one, during the course of a serious intracranial operation, to keep a fairly continuous plotted record—comparable to the kymographic tracings on which I had come to depend; armed, I say, with this small equipment, untutored in clinical neurology, and wholly ignorant of neuro-pathology, I returned to Baltimore and lay in wait for I knew not what. Certainly brain tumours could offer no expectation of livelihood, for up to that time, a dozen years since the opening of the Johns Hopkins, there had been admitted to the surgical service only 12 cases of brain tumour, most of which had been brought to light at autopsy.

A successful brain-tumour operation was a rarity, not the rule; and up to the beginning of the century treatises on the subject were apt to tabulate the 50 odd cases which had so far been reported in the entire literature as having survived an attempted extirpation. However, though the early hopes that these performances might safely rest on the tripod of anæsthesia, antisepsis, and localisation of cerebral function had been dashed, these pioneer operations of the 'eighties and 'nineties, in spite of their discouragingly high mortality, had disclosed an important fact which proved the beginning of a new era.

Matters Technical.—Needless to say, the victims of intracranial tumours ordinarily have headaches, and in course of time get blind; but many had observed that even though a cranial opening might fail to disclose a tumour—as it usually did—and even though paralyses or worse might ensue, the patient's discomforts for a time might not only be greatly alleviated, but, what was more surprising, his choked discs might subside with preservation of vision. These, then, must be purely pressure and not toxic effects of the growth; and Horsley's brilliant mind was quick to grasp and promulgate the idea of a premeditated craniectomy for the purpose of palliating the more distressing symptoms of these common lesions, irrespective of their nature and situation.

These early palliative operations, for which Jaboulay, I believe, introduced the term *trépanation décompressive* (1896), were usually made haphazard in any convenient portion of the skull, until Sänger, of Hamburg, suggested that the bone defects had better be made over the right posterior hemisphere, a relatively unimportant area of the brain from a functional standpoint. But the resulting protrusions covered by scalp alone were often so unnecessarily large and unsightly that other silent areas were sought, particularly ones where an undue herniation might be restrained by a securely closed muscle covering.

So it was that the temporal and suboccipital regions —on the one hand for supratentorial, and on the other for infratentorial lesions—were hit upon as preferential areas for the purposes of decompressions. And though these purely palliative procedures are nowadays less and less often requisitioned, they served a most useful purpose and saved a deal of suffering in their time. What is more, they served so to alter the attitude of the profession towards tumour operations that for a patient to become blind from an intracranial growth without some effort having been made to prevent this disaster, whatever else might be accomplished, came to be looked upon as reprehensible.

The old-time exploratory trepanations, which had unexpectedly resulted in giving relief from pressure, had usually been designed to expose lesions of the paracentral convolutions, and it was customary for the neurologist, in accordance with prescribed measurements and angulations, to mark out the fissure of Rolando on the scalp prior to the operation. Unfortunately, however, the very fact that tumours in this surgically accessible region were most frequently diagnosed, made it inevitable that a hemiplegia would ensue from discontinuity of the pyramidal fibres in the subsequent herniation.

Wagner, to be sure, had long before introduced the idea of an osteoplastic flap (1889), but this, in the hands of those who first attempted it was a matter largely of mallet and chisel, or of slowly nibbling a gutter in the bone with special forceps, of which there were many ingenious patterns; and it was not until the wire saw of Gigli was employed (1897) for the cutting of these bone flaps that the temporary osteoplastic cranial resection for exploratory purposes came to be a really practicable operation.

Neither patient nor surgeon likes the idea of a large cranial defect, however great the relief from pressure headaches; and both parties were in equal dread of the paralytic consequences of a protrusion involving the paracentral convolutions. The Wagnerian procedure promised to offset these complications, but unfortunately it was soon found that when an osteoplastic flap was turned down and the dura subsequently opened in the presence of tension which could not be relieved, it might be impossible to replace the flap because of the bulging brain; and it was for this reason, I assume, that Horsley abandoned the making of these flaps as a matter of general principle. The difficulties, however, can usually be overcome by what is known as "a combined procedure," in which the large flap essential for thorough exploration of the hemisphere is reflected with its base to the temporal region where, under the protecting muscle, a bone defect with opened dura can be made in the same situation and with the same purpose in view as when the ordinal subtemporal decompression is made from outside in. In the general run of cases the outward dislocation of the relatively "silent" temporal lobe then makes possible the replacement of the bone flap. . . .

But essential as the technical features of cranio-cerebral operations may be, these are dull matters to most people, and I prefer to dwell on what goes before and what follows them; on the preliminary studies which lead up to the diagnosis; and on the histopathological nature of the lesion so far as it affects prognosis and the surgical end-results. If the tumour question is to be covered as a whole, these are its more intellectual aspects; and my pupils, I am proud to say, have made contributions to diagnosis and symptomatology which are no less important than the additions which may have been made to mere craftsmanship.

---

[1] Horsley, in 1890, pleaded with the clinicians to agree on a definite probation period of drug treatment and suggested six to eight weeks, instead of as many months, as the time limit. Three years later Allen Starr proposed as a compromise a preliminary three months' trial with drugs, after which, if cure had not resulted, surgical measures should be resorted to.

Matters Diagnostic.—There were two important instruments—the ophthalmoscope and the perimeter—with which at the outset we had to familiarise ourselves, for it was an imposition to ask our ophthalmological colleagues to give the time necessary for the often daily observation of the changes in eye-grounds and fields that we were anxious to follow. Fortunately for us, the invention of the electric ophthalmoscope at about this time made possible the bedside employment of this indispensable instrument and did more to popularise its use than the vigorous though vain appeals to the profession, even of such as Hughlings Jackson and Clifford Allbutt, in the years gone by.

The perimeter of the two is the more difficult instrument, for it entails an interpretation of the patient's subjective responses, and Dr. Bordley and I were led at the very outset into a misinterpretation of our findings in describing the interlacing of the colour fields as an early evidence of pressure. However, this error, soon corrected, proved to be not wholly a liability, for it encouraged us and others to employ perimetry in the routine examination of all tumour cases; and this led to a series of papers on the distortions of the visual fields with Dr. George Heuer and with Dr. C. B. Walker, whose contributions to the subject are well known to ophthalmologists. Perhaps the most valuable disclosures were: (1) the progressive changes in the field mentioned in my last lecture as accompanying the usual hypophysial adenoma; and (2) the advancing homonymous defects on which we place great reliance in the diagnosis of temporal lobe lesions.

Though a brain tumour, even a large tumour as is well known, may be accompanied by no changes in the eye-grounds or fields, when these changes are present, as one or both usually are, and are followed from day to day, they prove the best possible gauge as to whether the process is advancing or receding. The neuro-surgeon, in short, needs for his daily use the ophthalmoscope and perimeter, no less than the physician, in following the condition of a consolidated lung, needs his stethoscope. No disinterested second party can be satisfactorily called upon for these purposes. What happened when the anatomist ceased to make his own dissections and employed a barber for the purpose is a matter of history; nor is this a far-fetched comparison.

These instruments, to be sure, the ophthalmoscope and perimeter, were in the hands of our predecessors, over whom, however, we are enormously advantaged by another instrumental aid to diagnosis, the X rays. Stereoscopy and the improvements in rontgenography which have followed the introduction of the moving diaphragm enables us in many cases not only to confirm our clinical diagnoses, to assure us by tumour shadows of the nature of the lesion and its precise situation, to lateralise it either by what Dr. Naffziger calls the pineal "shift," or by Dr. Dandy's method of ventriculography, but at the same time the rays give us promise of therapeutic aid as well.

But with all said and done, no instrumental aid to diagnosis can equal in importance a detailed and exact history of the symptoms in the chronological order of their appearance. This must ever remain our chief reliance, and the ability to elicit a dependable and correct clinical story is an art requiring perhaps even greater experience and skill than the making of a detailed neurological examination.

In assembling the clinical and laboratory data he regards as essential, the neuro-surgeon has evolved his own peculiar programme. This differs considerably from that generally followed by neurologists, since we have a somewhat different therapeutic objective; and in view of the great number of patients under the suspicion of harbouring a brain tumour who pass through our hands it would be humiliating did we not become more adept in making a diagnosis and giving a prognosis than those who see these cases less often, even had we not the added advantage of immediately checking our conclusions and correcting our mistakes by the invaluable experiences of exposing and dealing with the lesion on the living subject.

An operating surgeon is a peculiar animal. Of this perhaps no one is more aware than surgeons themselves, should they stop to analyse their conditioned reflexes. There is an unexplainable mental process that precedes what is known as a surgical inspiration, or to use an undergraduate's vulgarism, a surgical "hunch." This means nothing more than that after blindly puzzling and agonising over a difficult problem in the effort to determine just what course to pursue, there is a sudden and unaccountable clearing of obscurities, and an operator enters upon his task with a conviction of just what he will encounter and just what will happen, as though he were possessed of a sixth sense. I think most surgeons are more or less conscious of this state of mental preparedness for what to others may seem a desperate throw. But there is nothing uncanny about it; it is little more than the subconscious fusion of past experience which concentration brings to bear on a given problem. And as these inspirations in difficult cases are the outgrowth of personal and repeated bedside studies of the patient whose equation also enters into them, he who neglects this portion of his work and merely operates at the behest of another misses much.

No less should the surgeon and his staff shirk the responsibility of the detailed subsequent study of the tissues. Only by familiarising himself with the microscopic appearance of the lesions with which he is to deal and by making his own post-mortem examination of his fatal cases can the operator's experience be properly rounded out. He otherwise becomes a mere tool, misses all the intellectual satisfaction which should pertain to his work, and his technical facility is prone to become developed out of all proportion to the soundness of his judgment.

Matters Pathological.—On the old basis, when one group pronounced on the diagnosis, another group performed the operation, and a third was left to study the histopathology of the lesion, no one was sufficiently concerned thoroughly to study the case as a whole and to follow the victim of the disease to the end, for better or for worse. The surgeon unquestionably is, or should be, the person most vitally interested, the person most likely to take the trouble to assemble and weigh all the facts on which subsequent operations and the patient's ultimate fate may depend, the person, moreover, whom the patient is most likely to keep informed of his progress.

Twenty years ago it was the usual custom for the brain, on its removal at autopsy, to be promptly sectioned according to the time-honoured method of Virchow, which would assuredly bring to light a concealed lesion, but would at the same time permanently destroy the topographical relations of the lesion and its effect upon the brain as a whole, which, to the surgeon, is a matter of paramount interest. I therefore cannot sufficiently express my obligations to my pathological colleagues, first at the Johns Hopkins and in after years at the Brigham Hospital, for their generosity in making it possible for us to conduct our own post-mortem examinations on these cases.

This privilege has put in our hands a rare collection of tissues which are continually worked over; and since the brains have all been "fixed" in situ before their removal, it has been possible for us to study and restudy them at our leisure. There could scarcely be a more informing process than to review the clinical history with such a specimen in hand, and the gross examination of these tissues in this process has incidentally led to certain observations of interest relating to foraminal herniation, the vascular strangulation of nerves as a source of false localising signs, and so on.

But of even greater value has been the opportunity this collection of specimens gives for the periodical reinvestigation and reclassification of the tumours from a histological point of view as our familiarity with their differing clinical behaviour widens. . . .

So it is the neuro-surgeon's present ambition to concentrate upon one kind of tumour after another in a given situation, rather than to discourse, as we were once accustomed to do, upon brain tumours of all kinds on a broad front; for though they have certain behaviouristic features in common, their dissimilarities rather than their resemblances is the important thing. And there is an ever-increasing number of lesions which we can now, with a fair degree of accuracy, actually visualise and so be the better prepared to approach with the fewest strokes. One may gauge his shots better and be less likely to get into the rough when he is familiar with the course.

This allusion prompts me to mention still another element in all this not to be ignored. The results of a series of operations for a given lesion in a given situation provides a score for the surgeon to play against; and an audience north of the Tweed need not be reminded of the importance of this as an incentive in improving one's game. Only by a carefully checked and posted score, such as is now available both for the acoustic tumours and for the pituitary adenomas, can a tentative "par" for the procedure in question be established. So we are constantly striving to better our record on the double basis of lower mortality percentages and of longer and more livable survival periods in the case of the more rapidly growing tumours. A neuro-surgeon's responsibilities would be insufferable if he did not feel that his knowledge of an intricate subject was constantly growing—that his game was improving.

Certain mid-cerebellar gliomas of childhood which Dr. Bailey and I have recently described as "medulloblastomas," may serve to illustrate my meaning. These tumours, composed of undifferentiated cells, are among the most malignant and, from their situation over the roof of the fourth ventricle, rapidly fatal of all intracranial new growths. Five years ago we would no more have presumed to foretell the presence of one of these lesions than we would have ventured to remove it if it happened to be exposed in the course of an exploration. The average survival period of these cases, if left to run their course, proves to be six months from the time of onset of symptoms; this period may be prolonged on the average for another six months by a suboccipital decompression, with or without fragmentary removal of the tumour, whose activity, meanwhile, may perhaps be checked by radiation.

With this fore-knowledge we have become more and more radical in attacking these lesions, and now have a case living three years after what appears to be a total removal at a second operation; and there are a number of other children who remain free from symptoms well over the six months' period, which encourages us to feel that we are making progress and that the isolated three years' case was not purely accidental. But this matter of score, even for brain tumours of a single kind, becomes increasingly complicated as our tumour list has grown, and to keep abreast of our changing percentages and shifting diagnoses requires the undivided attention of a highly trained secretary, who keeps in close touch with the living patients and their physicians.

Someone has remarked that all this attention being paid to brain tumours has caused them to multiply. There is a modicum of truth in this somewhat Hibernian statement, for tumours unsuspected in times gone by are now uncovered, and it is not an exaggeration to say that more patients with presumed or proven intracranial tumours annually pass through a modern neuro-surgical clinic than were seen in a lifetime by those of a past generation who were interested in the subject. But though we may be more alert than our predecessors to recognise them for reasons that I have mentioned, the tumours with which we have to deal to-day, and which we have thus unwittingly bred, are from a percentage basis quite different from those of 30 years ago.

In a much-quoted paper read by Byrom Bramwell before the Medico-Chirurgical Society of Edinburgh on Feb. 21st, 1894, there is recorded a series of 50 personally observed intracranial tumours which had been disclosed at autopsy. In half of these cases the lesion was secondary to a scrofulous, malignant, or syphilitic process elsewhere in the body, and most of the others were clearly inoperable gliomas. Only 6 of these 50 cases, it is stated, might have been favourable for operation had a localising diagnosis been possible—a sorry outlook indeed for the surgeon of those days.

Nor were the tumour lists subsequently compiled by others from the general literature of the subject any more encouraging. One of the most optimistic of neurologists in his unchanging advocacy of surgical intervention in brain tumours has been M. Allen Starr, of New York, and yet in his compilation (1893) of 300 tumours there were 193 tuberculomas, mostly in children; indeed, tuberculous and luetic lesions comprise 71 per cent. of his assembled cases, whereas they represent less than 4 per cent. of our present-day tumour list.

Tumour Classification.

One essential to the dissemination of information is the coincidental adoption of some convenient term which serves to convey a definite meaning, however ill-chosen it may happen to be. In our early efforts to subdivide and tabulate our growing list of tumour cases we came to group them in the following three major categories: (1) the *tumour suspects*; (2) the *unverified tumours*; and (3) those *histologically verified*. The purpose of these subdivisions has been made clear from time to time by one or another of us, and needs at this time only a brief word of explanation.

In their desire to eliminate the possibility of an intracranial growth as the cause of persistent headache, disturbances of vision, convulsions, and so on, many physicians send their patients primarily to the surgical clinic for examination, and this group of cases puts our diagnostic capacity for differentiation severely to the test. They represent the old-time "pseudo-tumour" group, and among them occur examples of cerebral arterio-sclerosis, chronic abscess, aneurysm, cisternal arachnoiditis, subdural hæmatomas, multiple sclerosis, retrobulbar neuritis, mental derangements, and a multitude of other disorders which may be exceedingly difficult to distinguish from tumour and which are listed as "suspects" to be kept track of until the diagnosis comes to be assured in one way or another, should there be any immediate doubt about it. I do not know which is the greater source of humiliation—to operate unnecessarily upon a patient for a pseudo-tumour syndrome and to find merely an œdematous and arterio-sclerotic brain, or to send a patient to an asylum and learn a year or so afterwards that a frontal meningioma has been found at autopsy.

The unverified cases comprise the group of unlocalisable or inaccessible tumours whose existence is betrayed by an unmistakable tumour syndrome and for which temporary palliative measures may have been carried out. The list naturally contains many examples of tumour which will subsequently become verified by secondary operation or by autopsy, but it also includes those cases in which the story has already been closed and no post-mortem examination made. The criterion of verification rests on the microscopic examination of tumour tissue, for even if the lesion has been exposed at operation and its presumable nature recognised, without the actual histological study of a fragment removed for this purpose it is classed as unverified.[2] . . .

With this preliminary explanation to account for the presence in our records up to Sept. 1st of 513 tumour suspects and of 584 unverified tumours, we may turn to a more detailed consideration of the list of verified tumours grouped in Table I. under their family names.

TABLE I.—*Verified Tumours to Sept. 1st, 1925.*

Gliomas (varia)	492
Pituitary adenomas: Chromophile, 50; chromophobe, 154; mixed, 15..	219
Meningiomas (dural endotheliomas)	141
Neurinomas (acoustic)	100
Congenital tumours: Craniopharyngeal pouch cysts, 55; cholesteatomas and dermoids, 8; teratomas, 4 ..	67
Granulomatous tumours: Tuberculomas, 24; syphilomas, 13	37
Metastatic and invasive tumours: Carcinomas, 27; sarcomas, 13; hypernephroma, &c., 4	44
Papillomas (choroid plexus)	7
Blood-vessel tumours (pial): angiomas, 9; angio-endotheliomas, 5; peritheliomas, 3	17
Miscellaneous and unclassified	22
Total	1146

What will first of all be noted is the subordination, in this modern list, of the lesions which dominated those of some years ago. It is gratifying to see that the infectious granulomata represent so small a percentage of the cases. Whether this means that these lesions are disappearing as tuberculosis and syphilis are getting under control is not certain, but we may at least assume this is the case. Certain of the other tumours, the papillomas and the meningiomas, have been sufficiently commented upon in their connexion with the cerebro-spinal fluid pathway, as have the hypophysial adenomas and the craniopharyngeal cysts in their relation to the pituitary question. Special reports have been made on the cholesteatomas in the series, and during the past year Dr. Boris Fried has undertaken a special study of the blood-vessel tumours, some of which had gravitated to the group of unclassified tumours; and a few others, through inadequate study, had come to be included among the gliomas. Moreover, the familiar acoustic tumours which I have just cited as an illustration of the importance of concentrating upon neoplasms of a single type in a single situation have perhaps already had sufficient attention paid to them for a short address, particularly since I wish for the remainder of the time to dwell upon the hitherto much neglected growths which outnumber all others—the gliomata.

THE GLIOMAS IN PARTICULAR.

Mere numbers of cases, however, mean little. It is what is done with the few that actually counts; and numbers, even though they add to personal experience, may in reality prove a handicap to the advancement of knowledge by absorbing the time which might otherwise be spent in assuaging curiosity. All neuro-surgeons must certainly have had their curiosity aroused by the undependable behaviour of the gliomas after operation. Why were some apparently so favourable, others so malignant? How could one possibly account for divergent experiences, such as were had in cases like the following?

1. From the cerebellum of a young man of 23 a large tumour was removed in 1910. The diagnosis was "glioma." He was given a *bad* prognosis, but there has been no recurrence and he remains well and free from symptoms now 15 years later.

2. An apparently benign tumour was enucleated from the right hemisphere of a man of middle age. He was given a *good* prognosis. The pathological diagnosis again was "glioma"; and he died of an extensive recurrence within three months.

3. Two years ago a large subcortical tumour mass was removed from the left hemisphere of a woman of 43, who was rendered thereby almost completely hemiplegic and aphasic. It proved to be a "glioma" and the prognosis seemed hopeless. She has recovered, and except for a slight residual of her paralyses considers herself well, and is earning her livelihood as an expert photographer.

4. In a young man with advanced cerebellar symptoms a large "gliomatous cyst" of the right cerebellar hemisphere was merely evacuated. He remained well for 13 years when there was a return of his former symptoms, which led to a secondary operation, and a solid "glioma" was successfully removed from the situation of his former cyst.

5. A woman of 36 was operated upon in 1916 because of persistent Jacksonian seizures originating in the right face. There were no evidences of tumour and the bone flap was replaced. Nine years passed before she again came under observation. Her attacks during this long interval had been moderately well controlled by drugs, but she had begun to notice a progressive weakness of her face and arm and a defect in speech. Re-exploration disclosed an infiltrating "glioma" of the cortex.

These inexplicable experiences come readily to mind and the list might be indefinitely prolonged. Generally speaking, the gliomas have heretofore not only been the *bête-noire* of the surgeon, but a most amorphous subject to the pathologist. Yet they are unquestionably the most interesting of all intracranial tumours from many points of view. In our efforts to classify them from their surgical aspects in years gone by, about the best we could do was to divide them into the gliomatous cysts, the cystic gliomas, and the non-cystic gliomas.

We were aware, of course, that a tendency to cystic degeneration was not only common, but was in a certain respect favourable; and three years ago Dr. Paul Martin made a special end-result study of the gliomatous cysts, which served to show that the expectation of life after operation in these cases was at least as good as that for malignant tumours elsewhere in the body, such as cancer of the breast, for example. This was an encouraging disclosure, but it was not based on an histopathological study of the varieties of glioma which were concerned, nor were we then capable of differentiating them. Moreover, we had hit upon a most baffling type of lesion in our first effort to discourse upon a specific glioma in a given situation—namely, that involving the optic nerves and chiasm.

It is commonly assumed that a glioma, in spite of its degenerative tendencies, is a tumour of such hopeless malignancy that its attempted extirpation, however radical, is inevitably followed by recurrence; and there was some reason to believe that the mere operative meddling with the lesion was likely to stir it into increased activity. Here, then, was a lesion representing the chief bulk of our work, so far as tumour operations were concerned, cut off from the prospect of any surgico-therapeutic aid, apart from the mere temporary palliation of symptoms.

But in the course of a long and largely discouraging experience in dealing with these lesions, there had been a number of most unaccountable happenings. There were mystifying cases in the series like some of those just cited, in which either an extensive tumour, unquestionably glioma, had been found on the surface of the brain and been abandoned as hopeless; or in which a similar tumour was encountered and an obviously incomplete removal undertaken; or ones in which, after a radical extirpation, a pathological report of "glioma certain to recur" was returned; and yet the patients had remained well for years, free from any indications either of progression or return of the growth. From this only one conclusion could be drawn: that gliomas differed markedly in their behaviour under variable influences which were unknown, or else that there were many different kinds of them.

To the unpromising task of disentangling these true tumours of the nervous system, which so greatly preponderate over all other intracranial neoplasms, Dr. Percival Bailey and I set ourselves three years ago, he devoting himself to an investigation of their finer histology, far the most onerous and specialised part of the work, my small portion being to correlate his findings with the clinical histories and surgical experiences.

---

[2] We were led into making a single exception to this rule in the case of the gliomatous cysts whose yellow, clotting fluid contents are sufficiently characteristic to justify the diagnosis of glioma 99 times in 100. However, had we then known that the benign peritheliomas may undergo a similar cystic degeneration we would probably not have made even this exception, though these latter tumours are exceedingly rare.

To be sure, many different varieties of glioma have been described in the past, and in a sense no two gliomas are precisely alike if one takes into consideration size, manner of growth, situation, gross appearance, and microscopical architecture. But so complex had the matter of histopathological differentiation become that in our own pathological laboratory, as in most others I assume, the simple diagnosis of glioma, with little attempt at characterisation, served to cover the entire group. The only exception to this was in the case of certain distinctive tumours called neuroblastomas, which, as a matter of fact, we have now come to believe are not composed of neuroblasts.

It was necessary, of course, to begin at the beginning, and Dr. Bailey set out to familiarise himself with the normal glial elements and their reaction to the specific stains, it being a natural expectation on our part that could the several varieties of cells known to constitute the supporting substance of the central nervous system be identified in the normal tissues, the cytoplasm of these cells would not lose its specific tinctorial affinities even when they had acquired neoplastic tendencies.

Needless to say, the several glial elements have long been objects of study, even though neurohistologists, following Golgi, have been more interested in the neural than in the supporting tissues. The difficulty has been to find dyes with a specific affinity for the cytoplasm of the several glial elements which would leave the remainder of the tissue largely unstained; and to the contributions of Ramón y Cajal and his pupils neurology is almost wholly indebted for success in overcoming these difficulties. Others, of course, had been intrigued by the same problem, one of them that brilliant Scot, the late W. Ford Robertson, who 25 years ago described and pictured as "mesoglia" what Cajal calls the third element, and Hortega the oligodendroglia, those small round cells whose scanty cytoplasm is so difficult to stain and which abound near blood-vessels in the long fibre tracts of the central nervous system. But his method is one of the lost arts; at least, the platinum salt he employed, or believed that he employed, even in Bailey's practised hands, gives mediocre results not to be compared with Robertson's original preparations, some of which his son has been kind enough to send us. . . .

During the progress of this work descriptions of some of the more easily identifiable tumours, such as those composed of ependymal cells and of the pineal elements, have been published; and more recently the common mid-cerebellar gliomas of children,[3] composed of undifferentiated cells, have been made the subject of a special report.

Meanwhile the tissues of all the glioma cases in our possession were being recut and reinvestigated by the newer histological methods, and as the series up to January of 1924 proved to contain of the various types a sufficient number—viz., 412—of examples for the purposes of clinical correlation, this was then separately undertaken. Accordingly, from the clinical histories, tabulations were made of the survival period from the onset of symptoms, as well as from the time of operation for the cases up to this date, in correspondence with each of the histopathological subdivisions.

We had no preconception of what the results would show, though, had we been inclined to make prophecies before the figures were spread before us, it might have been anticipated that, other things being equal, the tumours composed of less well-differentiated elements would have the shortest antecedent history with the briefest post-operative survival period, and, conversely, that those composed of the more highly differentiated glial elements would have a longer pre- and post-operative story. We were, however, quite unprepared to find what the following highly condensed table betrays (Table II.), that certain definite tumour types show a longevity far and away beyond what one would expect for a glioma. The table, in other words, serves to show us the kinds of glioma that had seemingly responded so favourably to surgical intervention and to roentgenisation as to have been the source of our previous confusion.

TABLE II.—*Average Survival Period in Months for the Classified Gliomata.*

	Months.		Months.
Medulloepithelioma ..	8	Astroblastoma	28
Pineoblastoma	12	Ependymoma	32
Spongioblastoma multiforme	12	Spongioblastoma unipolare	46
Medulloblastoma ..	17	Oligodendroglioma ..	66 +
Pinealoma	18	Astrocytoma protoplasmaticum	67 +
Ependymoblastoma ..	19	Astrocytoma fibrillare ..	86 +
Neuroblastoma.. ..	25		

The details of this long study which is in process of publication need not detain us; it may suffice to say here that up to Jan. 1st, 1924, we had 412 so-called verified gliomas with which to deal. From these many eliminations had to be made: the cases "verified" merely on the basis of cystic fluid; those in which tissues had been improperly preserved for our purposes; certain atypical tumours which as yet baffle classification, and so on.

Table III., which lists the total number of verified gliomas in the series brought up to date, gives a sufficiently clear idea of the proportion of the tumours we have succeeded in classifying, and our reason for discarding about a third of them which fail to meet the criteria essential for the purpose.

TABLE III.—*Verified Gliomas to Sept. 1st, 1925.*

Verified by cystic fluid alone	54
Unclassified because differential study impossible ..	61
Unclassified gliomas of optic chiasm, pons or mid-brain: Optic chiasm, 12; brain stem, 19	31
Unclassified for other reasons: Atypical gliomas, 24; transitional forms, 6	30
Classified: Medulloepithelioma, 2; medulloblastoma, 41; pineoblastoma, 4; pinealoma, 7; ependymoblastoma, 6; ependymoma, 8; spongioblastoma—multiforme 100, unipolare 9; neuroblastoma, 3; astroblastoma 15; astrocytoma—protoplasmaticum 61, fibrillare 49; oligodendroglioma, 11	316
Total	492

Tables of classification are forbidding objects with which to punctuate a lecture. But there are one or two things to which, in passing, I may call attention. It will be seen in the first place that the 316 "classified" gliomas fall into three major groups—41 medulloblastomas, 109 spongioblastomas, and 110 astrocytomas. The medulloblastomas, to which I have already referred, are so malignant that when they once break through the limiting pia they tend to spread in the subarachnoid space in such a fashion as to have led to the term "sarcomatosis of the meninges." The spongioblastomas are scarcely less malignant and represent the so-called gliosarcomas of the older literature which have given their bad name to these tumours as a whole. But with the astrocytomas it is an entirely different story in view of their average survival period exceeding 86 months or over seven years. And when one considers that these 110 astrocytomas, together with the oligodendrogliomas which are equally favourable, represent approximately 40 per cent. of all the gliomas, the neuro-surgeon may feel much heartened in his tasks.

What all this means to us from the important standpoint of prognosis no less than of treatment is incalculable. But there is one thing more of which we are greatly in need—namely, the development of more rapid laboratory methods, if the clinic is to get the full benefit of these classified diagnoses.[4] What the surgeon must cultivate is the ability to tell with some exactitude just what kind of glioma he has exposed, and in the past it has taken so long to fix, to cut and differentially to stain the tissues that his picture-memory of the gross characteristics of the tumour, in spite of an operative sketch and a careful description, has become so faded before the exact returns come in, as to have lost much of its permanence. Moreover, the patient, as like as not, has in the meantime been discharged, and since the recollection of his particular lesion has become overlain by other impressions, it is difficult to get a dependable composite of one's operative and microscopical pictures.

---

[3] These are rapidly growing tumours which have been the source of great confusion since they have been variously described as "neuroblastomas," which is distinctly a misnomer, and as "round-celled sarcomas," because of their tendency to "infect" the leptomeninges, which is still worse. Dr. Bailey originally gave to these unmistakable tumours the name *spongioblastoma indifferentiale*, but since Strauss and Globus first used the term *spongioblastoma* for quite another lesion, we have gladly given way to them and have settled upon the term *medulloblastoma* as a suitable designation.

[4] Some tentative short cuts in this direction with promising results have been made by Miss Grace Hiller who has become highly efficient in the specialised technique of staining these tissues.

I may give an illustration of what this all implies by the story of a patient who at the moment has just left the hospital after the removal of a glioma from her left hemisphere. She is the wife of a physician whose experience with brain tumours had led him to expect the worst, and when what I took to be a large spongioblastoma was uncovered, I feared that his apprehensions would be fully realised. The soft, infiltrating tumour, so far as possible, was removed partly by dissection and partly by suction, and a thin block sent to the laboratory was put through by a shortened process in three days. It shows a pure protoplasmic astrocytoma which completely alters the prognosis in the case, to the great relief of all concerned. What we must search for, however, is a still more rapid process than this—one which will make it possible to get the histopathological returns while the operation is still in progress.

These, then, are some of the objectives towards which we are striving. I have from time to time put into writing some generalisations about the special field of neurological surgery. The first of these papers, written just 20 years ago, sounds on reperusal very juvenile in its discussion of the ætiology of choked disc; of palliative operations for purposes of decompression; in its chance remark that possibly someone some day might even venture to operate on a pituitary tumour. By slow processes we have come to broaden our horizon, but we neuro-surgeons do not for a moment forget that we are merely standing on the clustered shoulders of those herein unnamed persons who laboriously worked out for the benefit of our generation the development and finer anatomy of the brain, who discoverd the localisation of its functions, untangled the pathways of its impulses, determined the clinical expression of its lesions, bequeathed to us the instruments of precision we depend upon, laid the foundation-stones of modern cranio-cerebral surgery, and much more besides. We would betray their expectations of us had we not managed to cultivate a few flowering plants in the large field of neurology in which they did the spade-work.

There is, therefore, nothing novel in all this that I have laid before you—nothing, I fear, that Andrew Cameron would have felt was a distinct contribution to practical therapeutics. The complicated act of diagnosing, of localising, and of removing a brain tumour is based on long-established anatomical and physiological principles, and it is time we paid more attention to a detailed study of the lesions themselves. This will require a more intimate knowledge than we possess of their cellular composition, for which purpose aid must be sought from chemistry and biophysics, all of which merely shows how closely interlocked with other sciences any research in clinical medicine has come to be. And, in closing, I would like to quote a statement made by Ranvier in addressing the histologists in regard to his discovery of the clasmatocytes:—

> "Everybody knows [he said] that even objects which are quite apparent escape our observation when we are not yet aware of them, whereas we notice them at once after having learned to observe them. That is why it is so difficult to make discoveries, which afterwards seem so simple, one wonders as to the merits of having made them. What more easy to-day than to demonstrate the presence of glycogen in the liver! Yet Claude Bernard, who was undeniably a man of genius, only arrived at this after many years of research and by a series of repeated trials."

DIPHTHERIA IMMUNISATION IN A METROPOLITAN BOROUGH.*

BY C. W. HUTT, M.D. CAMB., D.P.H. OXF.,
MEDICAL OFFICER OF HEALTH, METROPOLITAN BOROUGH OF HOLBORN.

IN view of the satisfactory results obtained by R. A. O'Brien in the Holborn (Poor-law) schools, arrangements were made in 1922 to render the measure available for the general child population of Holborn. The results obtained are summarised in Tables I., II., and III.

The results of the Schick testing were very much the same as those found in all other urban areas; we have, however, analysed them in connexion with the immunity to diphtheria of various members of the families dealt with. The last column in Table IV. shows the number of exceptions (11·5 per cent.) to the expectation that positive reactions will be manifested only in the younger members.

TABLE IV.

No. of children in family.	No. of families.	Of which the members are—			
		All Schick positive.	All Schick negative.	One or more elders negative, younger positive.	One or more elders positive, younger negative.
2	97	71	6	13	7
2	43	19	4	14	6
4	14	5	—	4	5
5	8	2	—	4	2
6	2	—	—	2	—
7	2	—	—	1	1
—	166	97	10	38	21

In one family of five children, twins (F.) of 2–3 years of age were both positive; of twins of 7–8 years, one (M.) was positive, the other (F.) was negative.

In one family of three children one twin (M.) was negative, the other (F.) was positive, the latter had already been in hospital with diphtheria.

In one family of four, all Schick positive to the first test, two members were found to be Schick positive to the second test. The first of these (F. 4) was immunised some months previously to the second one (M. 1), and was further inoculated, being negative to the second test; the second child is not yet retested.

In another family, twins, one male aged 2 years when tested and one female aged 5 years when tested, were both Schick positive.

Routine Procedure.

The routine of the procedure carried out is as follows. The child is Schick tested at the Council's Maternity and Child Welfare Centre, and if susceptible to diphtheria is brought up by the parent at weekly intervals for the next three weeks for immunisation, and then at the end of another three months (formerly we tried for the period six to eight weeks) for re-Schick testing, when, if it happens to be still positive, it receives further inoculation. A modification of the routine occurs if from the Schick test it is seen that the child is particularly susceptible to protein reactions; in this case the 3 c.cm. of toxin antitoxin mixture are given in four or five doses at weekly intervals.

Although Park and Zingher recommend that Schick testing should only be applied to children over 5 years, it would seem inadvisable to dispense with the test as a routine at the present time in Holborn. It is a great satisfaction to nervous parents to think that there will be no inoculation unless susceptibility is proved.

Retesting is unpopular with parents, and the need for it does not help to increase their confidence in immunisation. Of 295 that have been retested 30

---

* Opening of discussion at the Annual Congress of the Royal Institute of Public Health, Brighton.

* Another child in same family (F.), aged 4 years, was negative.
† Three children in this group were members of one family: 2 negatives (M.), aged 2 years, (F.), aged 6 years; 1 positive (F.), aged 4 years.

In addition, one child re-Schick tested 15 months after 1 c.cm. T.A.T., was found positive, and two children retested after 3 c.cm. were on the information given by the mother considered to be slightly positive. Twenty of those positive on re-Schicking have been further inoculated, and ten of them further tested and found negative. Efforts are being made to continue the inoculation of the remaining ten. Of the 295 persons retested, 137 were males and 158 were females. Among the positive were 10 males and 20 females. Neither age nor interval seems to have any influence on the phenomenon. It would seem conceivable that some batches of toxin antitoxin or toxoid antitoxin might prove to be less efficacious than others. An analysis of the results obtained in Holborn would seem to indicate clearly that one batch of toxin antitoxin was less successful than the others; also that the toxoid antitoxin used was as efficacious as the toxin antitoxin. The toxin antitoxin used were all 3 L+ per c.cm. mixtures, the toxoid antitoxin contained toxoid diluted 1–10 with added antitoxin. (Table VI.)

TABLE VI.—*Batches of Toxin Antitoxin and Toxoid Antitoxin Compared.*

That considerable importance attaches to the retesting is shown by the fact that our one case of diphtheria among those treated occurred in a child who was given the routine three injections. The boy suffered from a severe attack of the disease, but recovered without any complications or sequelæ; his recovery was ascribed certainly by his mother to the inoculations of T.A.T. given after Schick testing.

A second case is said to have occurred in a boy (aged 8) also given the routine three injections. Two years later he was diagnosed (for the third time in his life) as suffering from diphtheria; no swab was taken. On admission to the M.A.B. Hospital he was first found to be swab negative, later swab positive, but was diagnosed as a case of diphtheria. The mother fortunately is still convinced that the boy did not suffer from diphtheria.

Reactions.

Our experience is that the reaction after the injection of the toxin antitoxin and toxoid antitoxin is in practically every case negligible. All we have to record is that in one child considerable swelling of the whole of the arm occurred, but the next day, when at the centre, she was running about and helping the other children eat their cakes; the swelling went down without any further result. Another, a boy of 10 years of age, his mother informed me, suffered with vomiting after each of his three inoculations and spent the next day in bed, but he and his mother stuck to it, and he was subsequently proved to have been satisfactorily immunised. In another child a small, hard, slightly tender nodule developed above the external condyle, but the tenderness only remained for a few days.

What of the Future?

Most of the attendances are the result of repeated efforts of persuasion and encouragement. Prejudice against inoculation is widespread; some of the most stubborn opponents of inoculation admit that if T.A.T. could be given in tabloid form or in spoonfuls they would agree to it. They object, in fact, to the introduction of animal products by means of a hypodermic syringe into the human body, but continued propaganda is sure to produce its results.

The aim of everyone who takes up the work must be to get all the children living in the area immunised as soon after they reach the age of 6 months as possible. In Holborn we have not reached this stage yet; the history of vaccination against small-pox suggests we never shall. But a local health authority is justified in considering that it has done all in its power to prevent loss of life and illness from diphtheria if it offers immunisation.

It might be expected that if the immunisation were carried out among the school population in a large town the parents would come to regard the procedure as more ordinary, and be prepared to allow the younger children to be immunised at infant welfare centres. Apparently it cannot be too often repeated that it is immunisation at a very early age that we want carried out; if it is delayed till school age half the deaths will have occurred. In London during three years, 1919–20–21, 52·5 per cent. of the deaths from diphtheria occurred under 5 years of age. Certainly if the immunisation could be completed at one visit the energy spent in looking up those failing to attend could be used in getting new recruits, and the parents would be spared much trouble.

At the present time efforts are being made to produce a substance which can be used to ascertain the susceptibility of the individual and at the same time to give some degree of immunity. Obviously experiments on these lines would seem to be concerned with the use of toxin as opposed to a toxin antitoxin mixture, but the methods used up to the present do not produce a toxin of sufficiently uniform strength to enable it to be used for routine immunisation.

Immunisation of Hospital Nurses.

A few words may perhaps be added on the need for the immunisation of hospital nurses. It would seem to be obvious that fever hospital nurses should be protected against diphtheria. I think it difficult to avoid the conclusion that all hospital nurses nursing in children's wards should be immunised. It must be within the experience of many of us that nurses in children's hospitals and subsequently the children themselves are often attacked.

It may be said that a nurse would have to be immunised against diphtheria, scarlet fever, and typhoid and the paratyphoid fevers; this is nothing. I imagine that many of us during the war were immunised against more diseases than these—those going East were protected against small-pox, typhoid and the paratyphoid fevers, cholera, dysentery, and plague. Who can show that we suffered any harm by taking advantage of the progress of science?

THE EFFICACY OF TRYPARSAMIDE IN THE CURE OF AFRICAN SLEEPING SICKNESS.

By CLEMENT C. CHESTERMAN, O.B.E.,
M.D. LOND., D.T.M. & H. CAMB.,
BAPTIST MISSIONARY SOCIETY HOSPITAL, YAKUSU,
HAUT CONGO BELGE.

EVER since the introduction, nearly 20 years ago, by Thomas, of atoxyl into the field of the therapeutics of trypanosomiasis, hopes have been alternately fostered and then relinquished in the attempt to cure certain human infections by the two human trypanosomes, *T. gambiense* and *T. rhodesiense*.

Complete and lasting success has accompanied the use of a variety of drugs in curing the hæmic and lymphatic infections which precede by intervals, varying from a few months to a few years, the migration of the trypanosomes from the blood-vessels and their entrenchment in the tissues themselves, especially those of the central nervous system. Up till the trial by Pearce (1920)[1] of tryparsamide, elaborated by the workers of the Rockefeller Institute for Medical Research, no valid claim had been advanced for anything but a temporary improvement in the signs and symptoms concomitant with this nervous involvement when really established, although the slighter degrees of it had been apparently arrested.

Before definitely making the claim for tryparsamide as a cure for such cases, based on our experience of the drug for the last four years, it may be well to review in brief the value and limitations of the main drugs and treatments in vogue up to the present.

Spontaneous Cure.

There exists a good deal of doubt as to whether this does really occur. One would expect from the well-recognised factors of varying virulence of the infecting strain of trypanosome and the differing degrees of natural and acquired immunity in the host that a fortuitous combination might result occasionally in a natural cure. The latest evidence in support of this contention comes from Todd (1924),[2] who reports eight cases found infected in 1911 alive and well in 1920, and one of these (no news of others) in 1924. He allows, however, the explanation of extreme chronicity as admissible. In our own series of 650 cases we have not a single instance of survival in good health among the few patients who have escaped, after diagnosis, any treatment whatever, although we are still watching a few cases who are apparently fit after but one or two injections. If some cases of early infection can result in a spontaneous cure, the consensus of opinion is that all cases (with the possible exception of those cited under the next heading) which have been proved to belong to the second class do eventually succumb to their infection.

Treatment by Atoxyl, with or without Tartar Emetic.

There is plenty of evidence to show that really early cases can remain to all intents and purposes cured after a single administration of one of these drugs—i.e., atoxyl, soamin, arsacetin, tartar emetic. Series of cases treated by one to three injections show varying percentages of cures according to dosage and the stage of disease reached, about which there is often no definite information. Even cases, the examination of whose cerebro-spinal fluid had proclaimed them to be in the second stage, have been apparently cured. Blanchard and Laigret (1924)[3] report five such cases alive and well from 6 to 15 years after treatment by atoxyl and arsenobenzols in doses so meagre and few that, in the light of experience with the vast majority of similar cases, such treatment could be disregarded as the primary therapeutic agency.

Opinion is now in favour of repeated injections of 0·015–0·02 g. per kilo body-weight, of atoxyl—i.e., maximum dosage. In a recent epidemic in our own region near Stanleyville about 250 patients have been thus treated in three years, and the percentages of cures and relapses to date are about equal. Treatment was carried out by native boys after diagnosis by the medical man, and consisted in weekly dosage of 1 g. to adults, to a total of 10 to 12 injections. Unfortunately, it was not practicable at the time of diagnosis to determine in all cases by lumbar puncture the exact stage of the disease.

The value of tartar emetic as an adjuvant to this treatment seems not to be very great, for although it is the stand-by of the veterinary surgeon, it is our opinion that its utility in human infections is confined to its use as a substitute for an arsenical should toxic amblyopia develop, or as a temporary trypanocidal agent in advanced cases where the onset of severe meningeal reaction is to be feared from immediate adequate dosage with arsenicals. Although tartar emetic alone has been known to cure even a case of infection with *T. rhodesiense*, yet no one would now use it to the exclusion of the arsenicals, and our experience goes to show that if there is any advantage in the combined treatment it is not commensurable with the increased risk and the visits required during the mass treatment of natives during an epidemic.

Treatment by the Arsenobenzols, &c.

The *arsenobenzols* have not been found to give results appreciably better than atoxyl, and their greater cost has prevented trial on a large scale. Now that continental firms are manufacturing "914" of excellent quality and selling it less than one-tenth the price charged by British firms, a further trial of these products might have been advantageous had not there been still better drugs available. The knowledge that they do penetrate the cerebro-spinal fluid suggests that they might have been more efficacious than atoxyl, the penetrability of which is probably less.

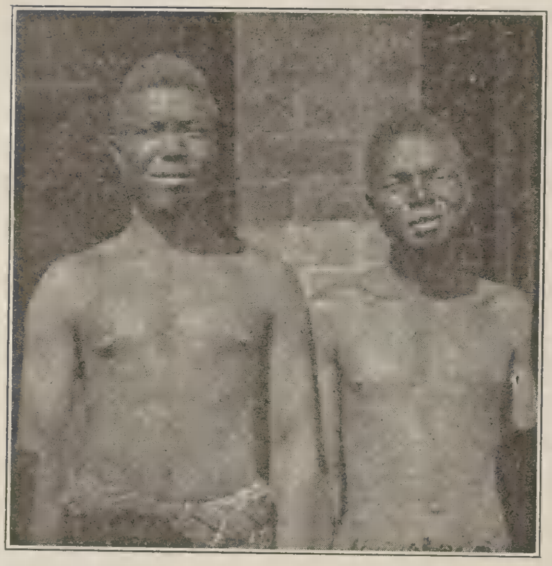
Intrathecal Injections of Drugs or Medicated Serum.—This method of attacking the nervous infection was tried by Reichenow in 1914, and retried by Marshall and Vassalo in 1920. Following their advocacy it was tried by many workers, including ourselves, but has now been abandoned as worse than useless.

Bayer "205," or Germanin.—Prolonged sterilisation of the blood and immediate temporary improvement in all patients, which continues in the early cases for many years, has proved the value of this drug. Yet our own series (1924)[4] of 17 cases in the later stages confirms the findings of Van den Branden and Van Hoof (1924)[5] that the value of this drug in nervous infections is less than that of atoxyl. This Dr. F. K. Kleine has admitted to us in correspondence on the subject, and is evident from the further reports received privately of his series treated in the Congo (1922).[6]

To recapitulate, therefore, there are a variety of drugs which are capable of effecting and maintaining sterilisation of the peripheral circulation for varying periods. Sterilisation is effected most quickly by tartar emetic, less so by atoxyl, and least quickly by Bayer "205," but the reverse order holds good for the maintenance of sterilisation when once effected. This brings out the real value of "Bayer" to the sanitarian concerned with the removal of infectivity. None of these drugs can, however, be relied upon to cure a case which has shown definite nervous involvement.

Cure by Tryparsamide.

Cases treated originally by Pearce and later observed by Van den Branden and Van Hoof, and cases by the last two workers alone at the Laboratory of Leopoldville, afford the very satisfactory figures of 100 per cent. cure of early cases, with unaltered cerebro-spinal fluid. We are able to report a similar success in five such cases, noted for from three and a half months to one year after treatment. Their figures for a series of 35 with altered fluid after an average observation of seven months was 45·7 per cent. still normal, but recent conversation with Dr. Van Hoof shows that the majority of these have remained well up till the present—i.e., an average observation period of nearly three years. These cases were not so far advanced and were more vigorously treated than our own series of 40 (1923 [7] and 1924).[8] Our latest published figure for non-relapse cases in this series was 40·5 per cent., but by the death of one of these (No. 146, Mbalika, the worst case of the whole series) the figure after two and a half to three and a half years falls to 37·8 per cent. It must be remembered, however, that these were all the worst cases one could find, averaging 630 cells per c.mm. in the cerebro-spinal fluid, and were treated by only one course of tryparsamide. The accompanying photograph speaks for itself.



Effects of tryparsamide in sleeping sickness:—*Left:* Case 73, three and a half years ago tryparsamide and 470 cells per c.mm. in the cerebro-spinal fluid. Apparently cured after 24 g. tryparsamide. *Right:* Case 150, 38 months ago tryparsamide and 760 cells per c.mm. in the cerebro-spinal fluid. Apparently cured by 26 g. tryparsamide.

Unfortunately, there are a number of cases which do not react so favourably to tryparsamide, so in claiming that the drug can cure we cannot claim that it is a cure for all cases. This fact is difficult to explain apart from the factors of varying virulence and different degrees of immunity. Personally, I feel that the latter is the most important factor. Pearce believes that the action of tryparsamide, which is only feebly spirillicide and trypanolytic in vitro, is due largely to its stimulation of natural defences.

That this defensive mechanism is largely dependent on the liver is suggested by work by Sei (1923),[9] who reported that extracts of the liver substance of Bayer "205"-treated guinea-pigs contained a greater concentration of therapeutically active agent in the infections of mice with *T. equiperdum* than those of any other tissue, not excluding the blood. It has also been shown that Bayer "205," though but feebly trypanosomicidal in vitro, becomes at once powerfully so when mixed with liver extract. Mignoli (1924)[10] has shown that the natural trypanosomicidal activity of adult human serum varies with the degree to which the liver cells are functioning. Acute diseases of the liver markedly, and chronic ones in less degree, exert very definite influences. The tolerance of arsenobenzols in syphilis varies also in a similar manner.

Clinical evidence is also forthcoming in support of this view, for all workers agree in the importance of removing hookworm from patients, the deleterious effect of the secondary anæmia produced by ankylostomiasis on the liver being well known. In two cases, complicated by an unrecognised bilharzial infection, we noted bad results during treatment; patients overdosed with atoxyl or tryparsamide often complain of abdominal discomfort and distension; a dirty tongue and highly coloured urine suggest liver trouble. They often put on a lot of flabby flesh, much to their annoyance, also suggestive of defective metabolism. Now that clinical tests for hepatic efficiency suitable for the busy clinician are being evolved, there seems to be a fruitful field for research in order to control treatment in the same way as for syphilis.

Suggestions for Treatment.

Our best control of treatment is the examination of the cerebro-spinal fluid for cells and albumin. This latter is simply effected by precipitation of the albumin in 1 or 2 c.cm. by trichloracetic acid 33 per cent., and comparison of the opacity with standardised bacterial emulsions.

It is convenient in treatment to use the common 10 c.cm. syringe, and as the dose of 4 g. should never be exceeded, a 40 per cent. solution is necessary in order that 4 g. may be given without refilling the syringe. This solution is arrived at accurately by the following simple rule, easily followed by native assistants. *Weigh x g. of tryparsamide and add 2x c.cm. distilled water.* For instance, 10 g. is dissolved in 20 c.cm. water and the resulting solution contracts to 25 c.cm. This is not too strong even for intramuscular injection.

The maximum tolerated dose must be arrived at gradually in advanced cases, but must be maintained whenever possible for at least ten injections, which may be either weekly or fortnightly. Adults will almost certainly relapse, if less than 0·05 g. per kilo body-weight is given, and children can stand almost double this amount—i.e., up to 0·1 g. per kilo, and will indeed tend to relapse without it. Thus a child of 14 weighing about 20 kilos can support as much as 2 g. weekly doses. Substitution of tartar emetic (not Bayer "205") for three weeks or a month, if toxic amblyopia develops, will generally allow resumption of former dosage again. In this connexion we may add that we have been using daily injections of sodium thiosulphate 0·45 to 0·9 g. at the first sign of amblyopia, but have no definite evidence worth recording at present as to its value.

A second short course should be given whenever possible six months after the first, the cessation of which is to be guided by progress and the condition of the cerebro-spinal fluid. It must be remembered, however, that the cerebro-spinal fluid will progress towards the normal limits subsequent to the cessation of treatment, if that has been thorough; and an excess of cells, even up to 50 per c.mm. may have entirely disappeared after three months.

If it is desired to combine the treatment with Bayer "205," we consider the most rational method is to alternate the two drugs for the first two or three weeks, giving one of each (not either) per week, and then continuing with tryparsamide. Continuation of Bayer "205" beyond the third injection is of very little use, expensive, and dangerous.

In conclusion, we affirm that tryparsamide can cure African sleeping sickness, although it does not always do so as at present administered, and that it should be the mainstay of our attack on trypanosomiasis. This principle has been adopted by the Belgian Government, which is responsible for the treatment of 50,000 cases annually.

I wish to express my thanks to the Rockefeller Institute for continued supplies of tryparsamide and to Dr. P. H. Manson-Bahr for much kind information and help.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF PSYCHIATRY
JOINTLY WITH MEDICAL SECTION OF
BRITISH PSYCHOLOGICAL SOCIETY.

THIS joint meeting was held on Oct. 28th, Dr. R. H. COLE, the President of the Section of Psychiatry, being in the chair.

Sir MAURICE CRAIG opened a discussion on the

EARLY TREATMENT OF MENTAL DISORDERS.

He said that the field of mental disease was much wider than that of physical disease, since the mind was a function of the whole organism and mental disturbance might affect any or all of the organs of the body. There were many schools of thought among those who studied the mind; the science had grown up through mysticism, metaphysics, and materialism to determinism and the "new psychology," and now one, now another aspect had been uppermost. The biological, the psychogenetic, and the physiogenetic schools held widely different theories and had each had their period of supremacy. The great danger in which the science stood was that rivalry between the adherents of different theories would cramp their scope and hinder their advance. Beneath each theory lay a fundamental truth, for which the student should search impartially and not allow his devotion to one aspect to hinder him from thoroughly examining the others.

The Importance of the Emotions.

In surveying broadly the psychological side of mental disorder, he showed that the outstanding factor in every one was emotional disturbance. The early training of a child depended for its efficacy on a harmonious balance of feeling, and might be completely interrupted if this balance were disturbed. This hindrance of mental growth would inevitably reflect itself later on his reasoning side. Keenness of perception and response to stimulus were, perhaps, the measure of mental capacity, but the more richly a man were endowed with these qualities the graver were the effects of any disturbance. The physical as well as the psychic reactions were affected; fatigue interfered with the function of the internal glands by permitting toxins to invade the system, and a vicious circle of cause and effect was formed. He would leave psycho-analysis to its particular exponents, and would content himself with suggesting that many of the patients they claimed to have cured would probably have shown as good or better results under some other treatment. On the subject of early treatment generally, he laid stress on the need for carefully watching children for signs of mental instability. Prophylactic measures should be introduced into schools to nip in the bud the effects of overstrain and other bad influences. He strongly deprecated the habit of explaining away early mental symptoms. Students should be trained to examine mental symptoms together with physical, and to allow them equal weight in diagnosis. Surgeons were particularly liable to neglect the emotional factor in a patient, which might nevertheless make all the difference between success and failure in an operation.

The Toxic Factor.

Passing to the physical aspect of mental disorder, he laid particular stress on the importance of toxins, both endogenous and exogenous. One school of thought even held that all mental trouble was due to the presence of toxins. Idiosyncrasy was a leading factor, and he had seen such harmless food as eggs or mushrooms produce acute delirium. He mentioned the work of several authorities on the effect of endocrine disturbances on the autonomic nervous system, and their part in anxiety and depressive states, and cautioned his hearers against prescribing gland treatment without fully understanding what they were doing, but also against neglecting it altogether.

Sleep.

All authorities, he said, agree in theory on the importance of sleep, but do not always allow it the paramount importance it should have as the only certain means of restoring wastage. It was foolish to fear hypnotics, for the risk of producing addiction was negligible. Some physicians could think only in terms of bromide, overdoses of which he had found damaged the lining of the stomach and sometimes produced confusion, though small doses were valuable. In spite of the feeling of many practitioners against the barbitones, he had found dial and medinal consistently useful. They improved the metabolism and induced a natural habit of sleep. Sodium veronal and luminal were both better than bromide. If sleeplessness were relieved early it left no terrors behind it. He concluded with a plea that the public should be instructed to seek advice as soon as mental symptoms showed themselves, and to enter a mental hospital voluntarily. The general prejudice against mental hospitals could be removed in time with proper instruction and increased accommodation for voluntary patients.

The Case for Psycho-analysis.

Dr. W. BROWN agreed absolutely that there was a physical aspect to every mental disorder, and that the body should be thoroughly examined for septic foci and other causes of toxæmia. Caries, tonsillitis, constipation, and subacute appendicitis were frequent sources of infection. The chief damage was done to internal glands, especially the thyroid. Fatigue was an important factor, which should be met by prescribing rest. On the whole, however, he thought that physicians did not tend to neglect the physical aspect of mental disease, but that they frequently paid too little attention to the psychic aspect of physical disease. An important cause of mental illness was failure to adapt at some period of life, and the physical symptoms produced caused further mental reactions, forming another vicious circle. The physician should learn thoroughly both the physical and mental situation before he prescribed for a case, and decide the best treatment for each side. Mental disease was broadly divided into functional and organic disorders; it was an axiom that no functional disturbance could occur without a corresponding change in structure, but a disorder was called functional if these changes righted themselves when it was cured by psychological treatment. The change of structure in an organic disease had to be treated physically; it was irreversible.

Hysteria and Hypnosis.

A very good example of the functional disorder where the change in structure was reversible was hysteria, the symptoms of which were extreme suggestibility, restriction of mental functions, and psychic automatism with the appearance of various phobias and obsessions. It was, like many other morbid mental conditions, due to failure of adaptation, and might, if neglected, develop into a psychosis. It was distinct from psychasthenia and the other psychoneuroses, but until it became chronic its symptoms were very indistinct. Its forms and causes differed and required different methods of treatment. He had found that hypnotic treatment gave splendid results in a great many cases of "war neurosis," where the symptoms were somnambulism, fits, and amnesia. The treatment was based on the fundamental psychological principle of re-association, and consisted in reproducing the somnambulism, fits, or key incidents by hypnotic suggestion, and allowing the subject to remember the process. By this means all symptoms were stopped in a very short time, the repressions that caused them were cleared up, and the mental integrity re-established. The test of success was a progressive diminution in the susceptibility of the patient to hypnotism. This method was, of course, nearly always combined with a detailed psycho-analysis.

Psycho-analysis.

Patients of psychasthenic and many other neuroses could not be hypnotised, and the methods he used were general analysis (an armchair interview where the patient talked of his life, assisted by the practitioner) and psycho-analysis, where he reclined in a semi-conscious condition and expressed the ideas and feelings that arose in his passive mind. The aim of the treatment was to give the patient encouragement, general re-education, and rest. It was generally a matter of months, but at the end the patient had acquired an autognosis and a general philosophy of life that went far to prevent him from failing again. He did not insist that distortion of the sexual tendencies was at the root of all psychic trouble. It was responsible for a great many, but the difficulties of several patients arose from the other two instincts, those of self-preservation and the herd.

Treatment of Severe Mental Cases.

He strongly advocated segregation and isolation, with the chief object of giving the patient rest from the social duties which were often the chief cause of his trouble. Mental hospitals offered the advantages of complete rest and the "atmosphere of healing," and the knowledge that many patients recover under the treatment they receive there, but they had the drawbacks of the society of mentally afflicted people and not enough psychological treatment, especially analysis. Many cases, however, required occupation, and he mentioned a clinic in which patients practised congenial handicrafts, games, and riding. The latter was an exceptionally fine stimulus for lethargic patients. Other items of treatment were milk, massage, and mental exercises. Skill in the choice of method was the chief requirement of the psychiatrist, and was not acquired quickly, but only after long and patient experience.

Discussion.

Dr. **Ernest Jones** questioned Sir Maurice Craig's statement that there was a school of thought which offered a purely psychic explanation of all mental disorder. Just as all good exponents of the physical causes recognised the psychic aspect, so Freud, Prince, and Janet took physiology and biochemistry fully into account. He agreed with Dr. Brown on the extreme importance of early diagnosis and prognosis, which were commonly overlooked by those who relied on palliatives; these, however, did not dislocate the patient's life like definitely wrong measures. A tentative analysis of two or three weeks was extremely useful in enabling a physician to decide whether a particular long and drastic course was likely to produce good results. These treatments were like surgical operations, some were obligatory, while others could be left to the patient's own decision.

Dr. W. H. B. **Stoddart** complained of the reluctance of the public to visit practitioners of any treatment with a "psychic" name, although they would trust neurologists. He disliked hypnotism, which he said increased the disorder in neurotics and was impossible to apply to psychotics. Psycho-analysts did not profess to discover sexual perversions but to uncover sexual repressions.

Dr. C. H. **Caldicott** said that he had often given 5–10 gr. of bromide regularly for as long as a year without the slightest harmful results.

Dr. A. E. **Carver** pointed out that a large proportion of the cases described as "mental" showed psychic and physical symptoms inextricably mixed, when it was difficult to decide which should have precedence of treatment. He was strongly against treating minor physical symptoms if he could help it, as the treatment held the patient's attention and aggravated his neurosis.

Sex and Internal Secretion.

Dr. H. **Corner** described the experiments of Steinach in grafting into animals the glands of the opposite sex. His argument was that every individual has the characteristics of both sexes, and if the "hidden sex" were allowed to grow more quickly than the actual it caused very severe conflicts which led in certain people to mental disorder. This was especially frequent in children of mixed race. It was therefore important that the relative likelihood of uneven development in children of international marriages should be established by experiment and predisposed individuals given gland treatment in their early years to restore the balance between the hormones of both sexes, for when the organs of secretion became differentiated no further modification from outside was possible. He went so far as to suggest prenatal gland treatment.

Dr. J. **Glover** spoke of the application of psycho-analysis to psychoses. It had delayed the degenerative process for some years in dementia præcox and had given good results in the manic-depressive form, a biennial depression having given place in one patient to a periodical neurosis. It had no effect on paranoiacs. Its use was not, however, confined to curing, since an experienced analyst could help and improve neurotics and in graver cases prescribe, if not a treatment, at any rate an environment that would give mental patients the best chance of improvement.

Dr. G. M. **Rudolf** stated that in a batch of general paralytics treated with malaria inoculation, 60 per cent. of those discharged cured or improved had been taken within 18 months after the first symptoms had appeared, but those in whom the disease had run for over 18 months numbered only 7 per cent. of the successes.

Dr. M. D. **Eder** said he was disappointed at hearing practically nothing but the virtues of psycho-analysis; he had hoped for a duel between the respective partisans of psychic and physical treatment. He mentioned the malaria treatment of general paralysis. It was undesirable to treat physical symptoms in hysterical and obsessed patients, as these symptoms would disappear with the restoration of mental health. Psycho-analysis had given good results in psychoneuroses, but no psychotherapeutic method had been very successful in treating psychotics. Results in the manic-depressive psychosis had been fair in paranoid cases if treated early. It was worth while taking risks in exploring its possibilities in dementia præcox.

The Blood-Sugar of Adolescent Psychotics.

Dr. R. N. Craig drew attention to the value in early dementia præcox and exhaustion states of blood-sugar tests as an indication of improvement. The starvation level in exhaustion cases often fell surprisingly low, but in most cases of dementia præcox it remained within normal physiological limits. Præcox cases showed a curve of the low, flat type after the glucose meal. Intensive treatment with thyroid and calcium lactate produced a great improvement in both the mental reactions and the physical condition of patients of both disorders, with a corresponding improvement in the type of their curves. He had produced a state of confusion in two cases of early paranoia by the injection of morphia and hyoscine; this had broken up their systematised delusions, but it was too early yet to say whether the improvement was permanent. He pleaded for wider instruction both of medical students and laymen in the danger signs of nervous and mental disease. In many mental disorders, if the practitioner were summoned in time and fully recognised the symptoms, he could avert what would otherwise be a complete mental breakdown.

The President, in summing up, deprecated any distinction between the physical and the mental factors. The physical illness should be treated on its own merits, whether it were related to the psychic disturbance or not. The mental picture was usually a counterpart of the physical.

Sir Maurice Craig, in his reply, dealt with the points raised by the exponents of psycho-analysis, and dwelt especially on the impossibility of diagnosing a mental case in the early stages, especially by its psychic reactions alone, which were often due to purely toxic causes. It was not even possible to draw a sharp line between psychoneuroses and psychoses, as the milder condition might develop into the graver if not properly treated. We should not be misled by names, but should treat each case on its merits.

Dr. Brown, replying, claimed for psycho-analysis the great merit that it gives a clearer insight into the mind than any other science, and for this reason no psychiatrist could afford to neglect it. It did not necessarily make sex or the narcissistic tendency the basis of every mental reaction. Hypnotism was certainly disastrous if used unskilfully, but both Janet and himself had found it invaluable. Hypnosis and hysteria were allied mental conditions.

SECTION OF COMPARATIVE MEDICINE

A meeting of this Section was held on Oct. 28th, Prof. F. T. G. Hobday, the President, being in the chair.

The President, before calling upon Dr. Andrews for his paper, delivered a short address, in which he passed in review the work which had already been done in the domain of comparative medicine, and spoke of the large field of investigation still awaiting attack. A remarkable observation which needed light was that one species of animal was immune to a disease which was fatal to another. Why, for example, was glanders so fatal to man and the horse while it was impossible to transmit it to the ox? He maintained that collaboration between the human and the veterinary students of disease had been greatly furthered already by the establishment of this Section of Comparative Medicine, and all over Great Britain this lead had been followed, as evidenced in the united meetings in the provinces between members of the British Medical Association and members of the National Veterinary Association. Such association perceptibly helped forward the mobilisation of the forces which were used in the fight against disease.

Advances in Knowledge on Plant Poisoning.

Dr. W. H. Andrews read a paper entitled Some Recent Advances in our Knowledge of Plant Poisoning. He said some forms of poisoning by plants were important by reason of the serious economic losses involved, but of particular interest was the occurrence of strange effects, or effects produced under unusual and unexpected circumstances. In Britain it was very difficult to obtain statistics on this subject; farms and holdings were usually somewhat small, when compared with those in the Colonies, and hence the total losses sustained by any one farmer were not such as to lead him to report them to headquarters or to require an investigation to be made. In addition, in a number of cases the diagnosis was not certain, and some losses attributed to feeding on certain plants were found not be due to that cause. But in South Africa, Australia, and the United States losses were much larger, and a larger proportion of the animals there were fed on natural vegetation than was the case in the United Kingdom. A further reason was that some of the countries were subject to severe droughts, causing serious shortages of ordinary foodstuffs. Long, one of the best authorities, agreed as to the difficulty of estimating losses from this cause, but said they were numerous, and that the aggregate financial loss was very heavy.

The present state of knowledge on poisonous plants Dr. Andrews considered very unsatisfactory; many plants were reputed poisonous which were not poisonous at all, while in a number of cases in which poisoning was attributed to a certain plant, it was founded on assumption, which was not borne out by careful investigation. Prof. A. J. Ewart, writing of the poisonous plants of Victoria, said it was common, when faced with a sudden outbreak of disease among animals, to incriminate some plant which grew in abundance in the vicinity. In County Dublin, Craig and Keir found that a certain disease appeared among animals in the spring and autumn, and many features suggested that the cause might be plant poisoning. There seemed reason to suspect a particular plant, a sorrel. Chemical analysis at first appeared to strengthen the suspicion, as it contained an oxalate in considerable amount. But Craig and Keir went a stage further and fed the sorrel to cattle; one bull consumed 269 lb. of it, and at no time did it, or the other cattle to which it had been given, show any ill-effects. Many plants, however, caused bad effects without having been suspected of doing so. Another source of error lay in the changes which occurred in the actual plant material, and but little was known on this. In many cases in which an apparently harmless material had produced illness, there was reason to believe the plant substance had undergone fermentative changes; some cases of illness had followed feeding with new-mown hay, and it had not yet been worked out whether the symptoms were due to an invasion of the hay by parasitic or saprophytic organisms. The latter might not cause any difference to the naked-eye appearance of the plant. A further possibility was the admixture of the plant material with material from some other source. Lathyrism in the human subject was well recognised in some Eastern countries, but evidence in regard to the amount required and the time necessary for the effects to develop had been conflicting. It had now been shown that the pure lathyrous grain did not contain any alkaloid of a harmful nature, and that to a number of kinds of animal it could be fed without harmful effects following. But cropped lathyrus was usually mixed with many weeds, and some of the latter gave rise to seeds which closely resembled lathyrous grains, such as a very common vetch containing a harmful principle. In a number of botanical species were included plants not quite similar morphologically, and probably differing considerably in chemical composition. Plants might vary in toxicity according to the soil in which they were grown, and differences were also observed in connexion with the season and the stage of development of the plant itself. Many plants were eaten only at a particular season of the year—i.e., when other products were very scarce. Dodd found, in Australia, a particular dermatitis in sheep due to skin sensitisation following exposure to the sun's rays, the rash occurring only on those areas of skin which were unpigmented. There had not been much work done on the changes in plants due to the presence of fungi in them. Mitchell, in Natal, worked at a particular condition in cattle associated with nervous symptoms, and he found the illness to be due to ingestion of harmless grasses which were mixed with an ergot-like plant. Lathyrism was found to have a definite incubation period, but little was yet known of the active principles responsible for the production of the condition. High fever was sometimes a symptom of plant poisoning; some animals developed a temperature, from this cause, of 107° or even 109° F. Marsh mallow fed to sheep caused bad symptoms in them, but not in horses and cattle. Chronic plant poisoning, he felt sure, was very frequent, and caused serious losses of stock. In some animals a certain time was needed after the feeding to develop symptoms; in one series the incubation period was 80 days. In domestic animals lathyrism showed a latent period whose length was about 54 days. In some cases the poisoning effects became manifest in a sudden explosive way; it might be that this synchronised with the breaking down of the liver cells in which the poison was harboured until then. When confronted with a disease which seemed like broncho-pneumonia, plant poisoning was not likely to be suspected, and even if suspected it might be difficult of proof. It was not easy to pick out the plant suspected, and when the symptoms developed the animal might have been taken some distance away from it. And there was much yet to learn as to why animals ate poisonous plants; hunger, especially in countries where droughts occurred, and the condition of the soil were among the factors. Animals which had been travelling were apt to be too hungry to exercise caution in the selection of their food.

Need for Biological Investigation.

Dr. Andrews said there was a real necessity for biological investigation in the first place—i.e., careful inquiry as to the effects of plants when fed to animals under their natural conditions, and the chemical and pharmacological investigation should only follow where biological inquiry showed the necessity of it. This would prevent much waste of laboratory effort and ability.

As to methods of prevention, the obvious method was to eradicate the offending plant, but that was a counsel of perfection, and in many instances it was economically if not practically impossible. Moreover, the property which made plants dangerous at certain periods was a valuable one at other times. More exact knowledge would enable advice to be given as to what stock must be kept off particular foods at certain periods. A further matter was that of dilution of foods which were poisonous when taken largely, so that no harm resulted. Symptoms in some instances only ensued after long-continued feeding on the offending plant, and in such cases the animals might be turned loose on such pasture only one or two days a week.

Discussion.

Prof. A. J. **Clark** said the question of the delayed action of poisonous plants was a very interesting one to him, and instructive parallels were afforded by ordinary pharmacological drugs. One kind of delayed action was that in which a particular drug would only produce a certain amount of action on a tissue for a particular time, and in order to cause a toxic effect it had to be repeated a number of times. Perhaps the best example of that was thyroxin. One dose of this, in any quantity, given to an animal caused no discomfort, but if this quantity were divided and given as several doses poisonous effects would follow. The determining factor in such instances seemed to be the length of time it was acting rather than the size of the dose. Examples were also found in metallic poisons, such as mercury diethyl. A dog was given some of this subcutaneously, and a month later no toxic effects had been observed, but two or three days later the dog became blind, and a week afterwards died of acute mania. Some arsenical poisons caused the same kind of effect, such as atoxyl, which could produce blindness long after it had been taken. He believed that people who worked in munition factories during the war were still dying from the late effects of T.N.T. on the liver cells. Similarly, lead poisoning, by its action on the arteries, might produce a cerebral attack at a remote date. He fully agreed that chemical investigations should be carried out only on those plants which biological inquiries had rendered suspect.

Dr. P. H. **Manson-Bahr** said there were a number of mysterious diseases in the tropics which so far had proved inexplicable on a parasitological basis. In India there was a cirrhosis of the liver which was very common, especially among Mohammedans, who did not take alcoholic drinks. Food might supply the explanation, as Dr. Andrews had said that cirrhosis of the liver in cattle could be induced by giving them a particular diet. A similar remark applied to the infantile cirrhosis among suckling infants in India, which occurred especially when children were born with the minimum interval between. In the case of pellagra, the rash appeared on surfaces which were exposed, so that the free areas of skin coincided with the parts of the body covered by the clothing. It seemed to be due, as in the case of the animals mentioned by Dr. Andrews, to the skin in the exposed areas being in a hypersensitive state.

Swine Erysipelas in the Human Subject.

Captain **Stowe**, in veterinary practice at Redhill, attended to show lesions of swine fever on his thumb and palm which he acquired in carrying out a post-mortem examination on a black pig which died from the disease. During the examination he made a small wound on his thumb, washed his hands in disinfectant at the conclusion, and then applied iodine. On the following evening there was a slight swelling at the wound and some inflammation. He applied lint soaked in 2½ per cent. carbolic and wore a rubber stall, and next morning the lesion had disappeared. Five days later a fresh lesion occurred on another part of the thumb. This continued to spread and fresh sites to occur until painted twice daily with 2 per cent. picric acid. The pig had a very virulent attack of the disease.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

FEVER HOSPITALS MEDICAL SERVICE GROUP.

A meeting of this group was held at the Society's house in London on Oct. 23rd, Dr. F. H. **Thomson**, the President, occupying the chair.

In the absence of Dr. E. H. R. **Harries** (medical superintendent, Birmingham City Hospitals) Dr. W. M. **MacFarlane** read his paper on the

SERUM TREATMENT OF SCARLET FEVER.

The speaker said that it was necessary to consider to what extent the results of serum treatment were due to (*a*) the serum itself—i.e., non-specific protein therapy; (*b*) specific antibacterial properties; or (*c*) specific antitoxic properties. It was difficult to estimate and especially to present graphically the results of any one form of treatment in scarlet fever, or to compare the results obtained by one means with those obtained by other means. After analysing some 1500 recent scarlet fever case-sheets and charts he could produce practically identical charts of similar clinical types of case which had had (*a*) no serum at all, the treatment being purely symptomatic; (*b*) normal horse serum; (*c*) diphtheria antitoxin, for the sake of its recent horse serum; (*d*) polyvalent antistreptococcal serum; and (*e*) specific scarlet fever antitoxic serum. Clinicians knew, however, that there were some signs and symptoms far too subtle to be amenable to a charting process. The estimate of any form of treatment except in the most general terms of success, partial success, or failure must ever remain one for personal judgment, and would, of course, largely be influenced by the type of clinical material available for its trial. In a disease which varied so greatly in severity and in type in different countries—and even in different parts of the same country—at the same time, and in the same country at different times, it was almost futile to attempt statistical comparison between the results obtained by individual workers employing the same therapy until very large numbers were available for analysis. He proposed briefly to discuss serum treatment in scarlet fever from three standpoints.

Non-specific Protein Therapy.—Quite recently Pontano had stated that he "has found that the serum of convalescents from scarlet fever, the serum of normal individuals, and normal horse serum are equally efficacious when injected intravenously. The mechanism of all three serums appears to be identical as far as can be judged from the effects." Claims had been advanced for the superior value of normal horse serum over antitoxin in diphtheria, but not many would be prepared to accept them. In a number of cases of scarlet fever of definite septic type he had given either normal horse serum or diphtheria antitoxin in doses of not less than 50 c.cm. intramuscularly, and had observed definite improvement, as shown by cessation of rhinorrhœa, diminution of adenitis, and progressive fall in temperature. But there were, of course, many cases of septic scarlet fever in which improvement in the septic process had followed purely symptomatic treatment.

Specific Antibacterial Serum Therapy.—Belief in the importance of the part played by streptococci in scarlet fever was, said Dr. Harries, no new thing. Klein had described a *Streptococcus scarlatinæ* in 1886. The earlier sera, in intent at any rate, had been primarily antibacterial and were produced from polyvalent strains of streptococci. The earliest produced by Marmorek (1895) had been a failure and others of similar type had followed it into limbo. Certain of the later productions of polyvalent antistreptococcal serum had, however, been employed with a measure of success in the strictly septic type of case when directed definitely against the septic manifestations. Claude Ker, in 1920, had held that the view that scarlet fever was primarily a streptococcal infection was one which was "being more and more discredited by modern research." Nobody had done more to investigate modern work in scarlet fever than Ker, and he had fully appreciated the significance of the discovery of the Dicks; of the bacterial sera, however, he had, on the whole, a poor opinion. Ker had later been one of the earliest to show that some of these sera presented either no antitoxic titre at all or so little that they would not produce a Schultz-Charlton reaction, the true nature of which—a toxin-antitoxin phenomenon—was first elucidated by Mair. Dr. Harries's own experience of polyvalent antistreptococcal sera had been fairly extensive. Although he was unable to recall any result approaching the "miraculous," yet he was sure that, given early and in sufficient dosage, the polyvalent antistreptococcal sera had frequently, but by no means always, had a favourable and sometimes a strikingly favourable effect upon the septic process. Given when this was well established or at any stage in inadequate dosage —nothing less than 50 c.cm. to 100 c.cm. intramuscularly was of value—they were practically useless. Such sera had no appreciable effect upon the primary manifestations of toxæmia.

Specific Antitoxic Sera.—In a series of 37 cases of scarlet fever Birkhaug had found that intramuscular injections of 15 to 85 c.cm. of serum from convalescent cases of scarlet fever caused a rapid improvement in the general symptoms, but practical difficulties made this method of treatment one of only exceptional application. Dr. Harries's own experience of convalescent sera given therapeutically was limited to two or three cases, and in these the results were inappreciable, owing (almost certainly) to the dose being too small. Zingher and others had employed citrated whole-blood from convalescents. One of the earliest sera which possessed definite antitoxic properties was Moser's (1902). Although still apparently employed on the continent, Moser's serum had fallen into disrepute, not because it was of no value, but because it produced very severe serum sickness. Dochez's was the type of the new sera obtained from horses immunised with the specific hæmolytic streptococci of the Dicks. More recently sera had been produced in America and in this country by immunising horses either with specific hæmolytic streptococci or with the specific toxin—the latter, of course, producing pure antitoxic sera. The Dicks claimed for scarlet fever antitoxic serum that "if given early in the disease there is a definite fading of the rash in 24 hours and improvement in the toxic symptoms. Antitoxin removes the toxic element and the subsequent course depends upon local infection of the nose and throat. After enough antitoxin has been given to relieve the patient of the necessity for combating toxæmia these local complications should receive careful attention."

Dr. Harries said that his experience and that of his colleagues with antitoxic sera had been entirely gained from about the beginning of this year with sera produced in the Wellcome Physiological Research Laboratories. Until a very much larger number of cases had been treated, and, moreover, a larger proportion of cases of great severity, their experiences could not be recorded as anything more definite than impressions. The type of case treated had varied from the moderately severe to the very severe. The first few cases had been treated with 20 c.cm. to 30 c.cm., and this dose was too small for a case sufficiently bad to merit serum treatment at all. Later cases had a minimum dose of 40 c.cm. intramuscularly. The largest total dose so far given was 70 c.cm. in two portions, and probably more marked and rapid improvement would have been seen in some cases had doses of 100 c.cm. or possibly more been given. In some cases serum had been given when toxæmia was well established; in others it had been intentionally withheld until some particular manifestation occurred in order to judge of the effect, if any, of serum treatment directed to that particular point.

Dr. Harries then summarised his tentative conclusions: (1) Reduction of pyrexia. On the whole pyrexia is reduced more rapidly by serum. With reduction in pyrexia tachycardia is also reduced. (2) Blanching of the rash. This is sometimes strikingly seen in 12 hours after injection, even with so little as 20 c.cm. of serum, but such rapid blanching of the rash only occurs in the earliest rashes—that is to say, in rashes less than 24 hours old. When the rash is more than three days old no appreciable blanching effect is produced, owing no doubt to toxin fixation in the tissues. Coincident with the fading of the exanthem has been the effect upon the enanthem. The engorgement of the fauces has rapidly improved and with this early rhinitis has ceased, this doubtless being due to the lessening of the inflammatory conditions of the fauces. The rash, however, is but an unreliable index of toxæmia. The hypertoxic case has, as a rule, a characteristically poor rash, and in estimates of the result of treatment too much attention need not be paid to what happens to the rash; a plentiful distribution of the toxin into the cutaneous tissues probably acts as a safety-valve. (3) Nervous manifestations. The toxin of scarlet fever is apparently an excitant of nervous tissues in contra-distinction to that of diphtheria, which is a depressant. It is upon the nervous manifestations that some of the most striking results following the injection of scarlet antitoxic serum are seen. Patients with severe delirium have in less than 12 hours become perfectly rational, and have been able to express themselves how much better they felt. (4) Septic complications. There is no rapid improvement in established septic conditions following the administration of antitoxic serum. (5) Late complications. Although the series was small and therefore no statement of any value can be made, there were no late complications in the cases treated with antitoxic sera—i.e., there was no instance of nephritis or carditis. (6) Serum sickness. This occurred in practically every instance and in the case of one batch of serum proved of exceptional severity; indeed, in one or two instances the serum sickness was quite as severe as the original attack of scarlet fever. Concentration of serum will perhaps reduce considerably the incidence of serum sickness.

Dr. Harries stated his belief that good scarlet fever antitoxic sera would do exactly what the Dicks had claimed and no more—that is to say, "remove the toxic element, and by relieving the patient of the necessity for combating toxæmia give him a much better chance to overcome septic manifestations." He discussed the practical difficulties of estimating antitoxic titre arising in the three methods used—namely, blanching of rash, passive immunisation of a Dick positive reactor, and neutralisation of toxin by antitoxin, as shown by performing a Dick test with a mixture upon a known susceptible person and obtaining a negative result. He concluded by referring to the views of R. W. Pryer, who, writing in the October issue of the *American Journal of Public Health*, stresses the importance of the presence or absence of a lytic principle in serum, and states that—

> "a serum (even an ordinary diphtheria antitoxin) which contains a high quantity of this principle will give a positive rash fading or Schultz-Charlton reaction. A non-lytic serum will not. *Streptococcus scarlatinæ* toxin is neutralised by a lytic serum. It is probable that the therapeutic value of a convalescent serum is partially due to this principle. . . . The serum of a horse may be strongly lytic at one bleeding and practically devoid of this property at another time. . . . There is the possibility that the serum of a horse, irrespective of its treatment, if obtained during the period of maximum lytic activity, will differ in its effect on scarlet fever from a serum obtained during the periods in which lytic principle is absent. Therefore it would be well, perhaps, to go cautiously in predicting that any methods of serum production will always give a satisfactory serum for use in the treatment of scarlet fever."

Apart from the above statements about lytic principle, said Dr. Harries, Pryer concluded that the mutation of bacteria is of common occurrence, and that scarlet fever is caused by a group of closely related organisms capable of intermutation by means of varying strength of bacteriophage-like principles. If these findings were borne out by subsequent work, they would go far to explain some of the difficulties and discrepancies encountered in work on the Dick toxin, the Schultz-Charlton phenomenon, and curative sera of any type.

Discussion.

The PRESIDENT said that he had treated 71 hospital cases with antiscarlatinal serum injected into the vastus externus. Of these, 31 were treated on the first day of the rash, 33 on the second day, and the remainder later. The average duration of the rash was shorter in the cases treated on the first day than it was in those treated on the second, and in 13 of the 31 first-day cases the rash disappeared within two days, whereas it did so in only 3 of the 33 cases treated on the second day. Of the 71 cases two were severe attacks of septic scarlet fever, and there were two severe initial attacks; the rapid recovery of the latter was remarkable. On the average the temperature fell somewhat more rapidly and became normal somewhat earlier in serum-treated cases, and complications were somewhat more frequent in cases treated on the second day of the rash than in those treated on the first. In the series of 71 cases 63 per cent. suffered from serum rashes and 25 per cent. from joint pains. There were no deaths. In dealing, as at present, with a mild type of scarlet fever, it was difficult, said the President, to estimate the true value of the serum treatment, but the more rapid fading of the rash with serum treatment seemed to be important.

Dr. DOUGLAS MCCLEAN stated that he had Dick tested nurses and children in the wards at the Hospital for Sick Children, Great Ormond-street, and that serum had been given to those who had positive reactions. The dose had been 5 c.cm. at first, but that had not always produced a Dick negative, and the dose had therefore been increased to 10 c.cm. As regards the protection of the children, the results had not been conclusive.

Dr. G. A. BACK (London Fever Hospital) said that he had treated some 30 cases with serum, but it was difficult to estimate the effects of treatment, particularly in view of the mildness of the scarlet fever prevalent.

Dr. E. W. GOODALL (N.W. Hospital, M.A.B.) also remarked that the difficulty was to find any bad cases; amongst the last 300 cases of scarlet fever admitted to his hospital there had not been a single death. In the few cases that he had treated with serum recovery had certainly been more rapid than he would have expected, but those cases could not be looked upon as severe, and in the ordinary way they would have got well without serum treatment. In the cases referred to the dosage had been 30 to 40 c.cm., and sometimes more, and in only one of them had there been an attack of serum sickness, and that had not been worse than what might occur with injection of antidiphtheria serum. Dr. Goodall suggested that it would be better to use the word "refined" instead of "concentrated," as applied to various sera, as he understood that the process aimed at getting rid of the superfluous proteins.

Dr. R. A. O'BRIEN (Director of the Wellcome Physiological Research Laboratories) said that it was necessary to define what sera were, and to find a method of deciding whether a serum was good or bad. There was practically no laboratory test of any value yet discovered, but hope had not been given up. The American method of testing by obtaining passive immunisation of a Dick positive reactor gave results which were very difficult to interpret. It was very difficult to provide serum which was of undoubted high antitoxic value, and it would be unfortunate if improper claims were made for the serum treatment of scarlet fever; unreadiness to draw conclusions before an adequate number of cases had been treated was to be encouraged. There would be no trouble in getting unlimited supplies of serum once it was known to have a definite antitoxic value. The sera of his firm had passed the American standard. The fact that cases of mild scarlet fever treated with serum had suffered more from the serum pains and rash than from the disease itself was an objection to its use in such cases. The passive immunisation test was undoubtedly the best available, but it must be considered whether or not the exposure of people to test the antitoxic value of serum was legitimate. Dr. O'Brien quoted figures supporting the view that complications were less common in cases treated with serum. With regard to Pryer's paper on the lytic method of testing, he withheld his opinion.

Dr. BACK said that a certain amount of delay was entailed by the use of the Schultz-Charlton test, but the majority of patients would receive their curative dose within 24 hours. The shortest period had been four hours.

Dr. A. E. A. PEARSON (Leeds City Hospital) stated that he had used the serum in a small number of cases and had noticed that the temperature had fallen in from 12 to 24 hours in nearly every instance. He had used 10, 20, and 30 c.cm. doses, but expense could not be overlooked. The cost of the American serum he had procured had been 25*s*. per 10 c.cm., so that doses of 80 or 90 c.cm. would involve a heavy expenditure. He urged the need for a standardised antitoxin, and expressed the hope that it would be a practical proposition in time.

The PRESIDENT said that at the N.E. Hospital they had been increasing the dosage, and in the last few cases had given usually 60, 80, 100, and even 120 c.cm., but there was no clear evidence that the large dosage produced any better effect than the small ones.

CARDIFF MEDICAL SOCIETY.

THE first meeting of the session of this Society was held on Oct. 13th, when Dr. R. CAMERON delivered his presidential address on Some Aspects of Gastric Function in Relation to Symptoms. Taking Ryle's classifications of dyspepsias as a basis, he reviewed the functional and organic disorders, emphasised the similarity of subjective symptoms arising from both, and compared the prevailing views on the motor, secretory, and sensory functions with those which have hitherto been taught. He reviewed the work of Carlson on hunger and appetite and pointed out that the factors producing normal sensations may, when exaggerated, lead to those conscious responses which are recognised as subjective symptoms. Dr. Cameron discussed Hurst's important contributions to this subject, which disproved any sensory response of the mucous gastric membrane to varying stimuli, demonstrated reflex hypertonus in response to local and distal irritation, and established this as a cause of delayed pain. The researches of Bennett and Ryle on fractional gastric analysis were dealt with to show that extreme variations of acidity occur without any gastric symptoms being evident and apparently without any disturbance of metabolism. In a series of mental patients without any gastric symptoms which Dr. Cameron had examined, a number showed achlorhydria or hyperchlorhydria. The conclusion drawn from recent work on gastric function in health and disease was that normal sensations result from tonus and tension of the muscle, and that subjective symptoms are most easily explained on a similar basis.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.

AT a meeting of this Society held on Oct. 22nd Mr. H. BLACOW YATES read a paper on

Acute Osteomyelitis

based on 38 cases treated in the Sheffield Royal Hospital during the past five years. In 70 per cent. of them there was a history of a recent accident, and the majority presented a focus of staphylococcal infection at the time of admission to hospital. The pathological lesion insisted upon was metaphyseal hæmatoma, the result of trauma, which became infected by staphylococci circulating in the child's blood, though the presence of these staphylococci had produced no previous symptom. In considering the diagnosis remember the rarity of acute articular rheumatism in children under 15 years. Of six cases of acute osteomyelitis having more than one lesion at the time of admission to hospital, two showed infection of three bones and in the remainder two bones were involved. The bones affected were often on opposite sides of the body. Four of these cases recovered, two of which had a positive blood culture. Mr. Yates urged the necessity of opening the medullary cavity when external appearances were normal and discussed the factors contributing to the 18 per cent. mortality.

Mr. R. ST. LEGER BROCKMAN read a paper on

Obstruction of the Small Intestine

without reference to strangulation. He discussed the reasons why kinks were not removed in the intestine, as they are in a garden hose, by the pressure of the contents. The rapidly increasing stimuli caused a state of tetanus or spasm in the musculature of the small intestine, and as this tissue became fatigued another phenomenon of plain muscle appeared, the so-called idio-muscular contraction, which remained localised and showed no tendency to move on. The retraction ring observed in cases of obstructed labour was the best example of this condition. In all cases of obstruction there were two factors at work: the first physical, the second physiological. The increasing content of the bowel and bacterial invasion inaugurated a vicious circle, and often resulted in a partial volvulus of the small intestine. The really important thing to be considered was early diagnosis. Acute spasmodic abdominal pain, vomiting, and shock were the earliest signs and symptoms of acute obstruction. Under these conditions the only safe course to adopt was to assume the presence of obstruction until the opposite was proven. The most valuable means of diagnosis was the stethoscope. The peculiar musical tinkle of air and fluid in wearied intestine was a distinctive sound, never to be forgotten when once recognised. It could be heard at a very early stage through the abdominal wall and could often be elicited by the same manœuvre as that used to obtain a gastric succussion splash. Obstruction of the small gut demanded the surgery of the fingers rather than of the hands, and the operation should be done through as small an incision as possible. To obtain this ideal the most painstaking efforts at locating the site of obstruction were called for. The careful use of the stethoscope, and the position in which the spasm of pain fell off, or what might be called "the march of the pain," were valuable evidence in this search. Surgery in early cases should aim at simply relieving the obstruction; in later cases, where an advanced degree of distension and toxæmia were present, enterostomy should be done. Circumstances alone would decide whether this should be external, or internal into the transverse colon. Mr. Brockman observed that after the actual obstruction had been relieved, the practice of emptying the intestine by means of Moynihan's tube was most useful in some cases of extreme distension. It was essential to remember that the tube should be introduced through healthy intestine below the site of constriction.

In the discussion that followed the papers Prof. A. M. CONNELL, Mr. ERNEST FINCH, Mr. GARRICK WILSON, and Mr. ARCHIBALD CUFF took part.

PATHOLOGICAL SOCIETY OF MANCHESTER.

AT a meeting of this Society held on Oct. 21st, Prof. E. D. TELFORD being in the chair, Dr. C. P. LAPAGE read a paper on

Diathesis in Children.

Diathesis, he said, is not acquired, it is an inherited peculiarity of constitution which cannot be eradicated though it may become quiescent. An acquired condition such as rickets is not diathesis because such a state can be cured and is not a lifelong condition. Diathesis is a state of the human organism in which there is an inherited peculiarity of constitution so that the individual tends to exhibit either certain reactions in response to irritating factors or certain weakness of resistance. It is familial rather than racial or national. Dr. Lapage went on to deal specially with two diatheses, the exudative and the nervous. The exudative diathesis is an important factor in determining the reaction of children to disease and to faulty metabolism. Asthma, eczema, hay fever, and angio-neurotic œdema are the well-known signs, but curd-dyspepsia, milk-intolerance, urticaria, and croup are common in infants of this diathesis and in later childhood. In addition there may be cyclical vomiting, mucous colitis, and other signs very similar to gout in adults. Children of exudative diathesis are of a pale lymphatic type and are restless and irritable. Irritants are concerned in the production of signs of the diathesis; the individual is exudative and may be sensitised. External irritants are: (1) Foreign proteins derived from animals or from plants, food, or bacteria; (2) metabolic faults from animal fats, acids, fruits, wholemeals; (3) climatic factors from bracing seaside places and east winds. Internal irritants are from infections of the respiratory, digestive, or other systems, and also from infected lymphatic glands. In the nervous diathesis the child has a weak spot in the reactions of the nervous system, and as a result of infection or overstrain may show disturbed nervous reactions, tachycardia, irritability, moodiness, various phobias, night terrors, and even fits may occur. Babies with pyloric spasm are of the nervy type, and some babies who find great difficulty in feeding do so because they are nervous. Genuine hysteria may be present in infants.

Reviews and Notices of Books.

The Pathology of Tumours.

Second edition. By E. H. Kettle, M.D., B.S. Lond., Professor of Pathology and Bacteriology, Welsh National School of Medicine, Cardiff. London: H. K. Lewis and Co. 1925. Pp. 285. 12*s.* 6*d.*

There are two ways of looking at tumours. They can be regarded as purely adventitious and possibly avoidable formations, as "purposeless" pests, the sole discoverable object of which is to prevent overcrowding of our globe. There is a second and more scientific light in which tumours can be regarded—namely, as variations or anomalies of growth, comparable with other departures from the "normal" standard, to which practically every cell in the body which has not ceased to perform its physiological functions is liable. Viewed in this light the problems of tumour formation are susceptible of study upon general biological lines. A beginning has been made in this direction, but the teaching on the subject lags behind the advances which have been made. Prof. Kettle is one of the few pathologists in this country who are qualified to improve the teaching, and he is to be congratulated upon the way in which he has faced and overcome the difficulties. The second edition of his "Pathology of Tumours" is a model of conciseness and deserves to be ranked with Kaufmann's "Lehrbuch." It has been thoroughly brought up to date, and chapters have been considerably altered, if not rewritten. The student who, after reading it, fails in the higher examinations must not blame this book. The chapter upon the Experimental Study of Cancer is invaluable for everyone who has been unable to keep in touch with the latest developments. If we regret an omission in the book, it is that full references are not given to all the writers quoted in the text.

Possibly because he is writing a text-book intended primarily for students, Prof. Kettle seems to us to under-estimate the variability of tumours, a feature that they share with all living tissues. In the chapter upon the basal-celled carcinomata (in which, by the way, he is not quite just to Krompecher when he suggests that they were so named in the belief that they alone—and not all the cutaneous carcinomata—arise in the basal cells of the epidermis, which alone retain the function of division) he discusses the possible origin of rodent ulcers in hair follicles or sweat glands. But it is a well-established fact that these structures share in the epidermisation of scars. Then why should not a tumour that originates in epidermal cells mimic the minute and really insignificant structural differences that arise during the natural development of the skin and its appendages, regardless of its exact site of origin? Another question which might be asked is this, Are not keratinisation and the production of "colloid" expressions of functional zeal on the part of a tumour, however misguided it be, since they correspond with physiological differentiations? They can hardly be regarded as degenerations. Morphologists may also question the importance the author attaches to the endotheliomata. We agree that the name has been much abused in the past. It could with advantage be discarded and replaced by "angioma," "angiosarcoma," and so forth. Why label a salivary tumour "endo-thelioma" when Prof. Kettle tells us that "it is now pretty well agreed that it is derived from epithelium"? These and similar difficulties would be largely overcome by adopting Albrecht's teaching and frankly admitting that *all* tumours are malformations, and that, although the majority of them are well-defined species, many cannot be separated from hyperplasias and other anomalies of growth.

The book is well got up. The illustrations are good, especially the histological drawings, which we believe are the work of Prof. Kettle's own hand. The present edition is a worthy successor of the first, and will occupy a sure place among books of reference.

Urology.

The Radiological Examination of the Male Urethra. By G. L. S. Kohnstam and E. H. P. Cave. London: Baillière, Tindall and Cox. 1925. Pp. 115. 15*s.*

In this work the authors give the results of their method of investigating the urethra, which has been used for the last five years, but has not yet found general favour amongst urologists. This has been due partly to the fact that urethroscopy and cystoscopy give such accurate information that other methods are, as a rule, unnecessary, and partly to the difficulty of acquiring a reliable technique and interpreting accurately the urethrograms obtained. This book gives a full description of a satisfactory method of injecting the urethra, and, by supplying a large number of interesting plates, gives the reader an opportunity of learning what facts may be deduced from urethrograms. The opaque fluid employed by the authors is lipiodol, diluted with four volumes of sterile paraffin, and it is injected under a constant pressure recorded by a mercury manometer. Radiograms are then taken under different conditions—between injections, during injections, and with the bladder constricted or relaxed. Full details are given concerning the best positions, both of the patient and of the radiographic apparatus. The second section of the book deals with the interpretation of negatives. The conditions in which the authors consider a radiological examination of the urethra of the greatest use are stricture, prostatic enlargement, and obstruction following prostatectomy. It is interesting to note that as a result of their investigations they have come to the conclusion that the sphincter action after prostatectomy is undertaken not by the compressor urethræ muscle, but by a portion of prostatic urethra that has been left behind.

Although it is unlikely that radiological examinations of the urethra after distension with an opaque fluid will ever take the important place in urology that pyelography has done, it must be admitted after reading this work that the method may be of considerable use in special cases. Thus, in old-standing strictures, in which treatment by excision is under review, a urethrogram will furnish valuable knowledge prior to operation as to the amount of urethra that it will be necessary to excise in order to obtain a satisfactory result. The authors are to be congratulated on their addition to our knowledge of radiography of the urethra and on having presented the results of their investigations in a readable and easily assimilated form. Their book should certainly be found on the shelves of all specialists in genito-urinary troubles.

Empyema.

Some Fundamental Considerations in the Treatment of Empyema Thoracis. By Evarts A. Graham, A.B., M.D., Member of Empyema Commission, U.S. Army; Professor of Surgery, Washington University School of Medicine. London: Henry Kimpton. 1925. Pp. 110. 10*s.* 6*d.*

Prof. Graham's essay was written in 1920, and the delay before publication has given him a chance to criticise in an addendum articles upon the same subject which have appeared in the meantime.

No attempt has been made to cover the subject of empyema as a whole, and the author founds a therapeutic procedure on general principles. Prof. Graham states that the mortality-rate of streptococcal pneumonia associated with empyema in certain military camps during the influenza pandemic was actually above 70 per cent. By the adoption of the cardinal principles discussed in the essay the mortality was reduced to 4·3 per cent. The essential features of these principles are three: (1) careful avoidance of an open pneumothorax in the acute stage; (2) the prevention of a chronic empyema by the rapid sterilisation and obliteration of the infected cavity; and (3) careful attention to the nutrition of the patient. It is with the first of these principles that the greater bulk of the author's treatise is concerned. His insistence upon its importance is founded on observations of the experimental production of pneumothorax which prove that previous conceptions of its mechanics are incorrect. It is often thought that the two pleural cavities are kept rigidly exclusive by the mediastinum. But the latter opposes only a very slight resistance to pressure unless it is previously diseased and thickened by long-standing inflammation. An open pneumothorax on one side, therefore, leads to compression of *both* lungs. A lung does not necessarily become collapsed and functionless even if the pleural opening is larger than the diameter of the glottis, and a bilateral open pneumothorax is not inevitably fatal as it would be, of course, if collapse of both lungs were to ensue. The maximum opening into a pleural cavity that can be safely undertaken depends upon the relation between the amount of air entering the lungs and the amount which enters the pleural cavity. Any condition which reduces the "vital capacity" or increases the demand for oxygen will diminish the size of the opening compatible with life.

During the pre-critical stage of pneumonia the amount of air entering the lungs is for several reasons diminished. Later, with a relatively higher vital capacity the thorax may be opened with less danger of respiratory embarrassment, as will also be the case when, through past inflammation, the mediastinum is relatively rigid. These conclusions are in accordance with clinical experience. Repeated aspirations should be substituted for operation in the pre-critical stage. If frank pus develops, operation can be done later, and is, if possible, postponed till the condition of the patient is favourable. Some years ago[1] Dr. A. Abrahams described 116 cases of empyema under his care, in 86 of which aspiration alone led to complete resolution.

The book is a little wearying by a tendency to repetition, but it is very convincing, and the conclusions will be attractive to those physicians and surgeons who have more or less empirically adopted the recommendation for which Prof. Graham supplies theoretical reasons.

AUSTRALIAN TOTEMISM.

A Psycho-analytic Study in Anthropology. By GÉZA RÓHEIM, Ph.D. With an introduction by M. D. EDER. London: George Allen and Unwin. 1925. Pp. 487. 35*s*.

THERE is a bewildering amount of material concerning the totemism of the Australian aborigines, and observers like Spencer and Gillen, who lived among the Arunta tribes of Central Australia, have made detailed records of beliefs and ceremonies which will soon be things of the past; but no theory as to the origin of these complicated systems has been generally accepted. Róheim, following Freud in his work on "Totem and Taboo," studies their psychic structure and claims to trace their evolution from the period of the supposed primitive horde in which the brothers unite to kill the father in order to secure possession of the women of the horde—the primeval Œdipus situation. Granting that this situation exists as an unconscious fantasy that can be revealed by individual psycho-analysis, it still seems a far cry to the postulation of a stage in human development in which it was an actuality. If we grant that, and a good deal more of psycho-analytical theory, we may follow Róheim's ingenious explanations of the extraordinary facts of Australian ethnology. Even then there remains a feeling that his speculation is too facile, as in the picture drawn on p. 389 of the events after the killing of the father, when the horde "would come back to stone the corpse a second time as they had stoned the man when he was alive."

Yet the application of psycho-analytical findings to explain totemism is more than a tour de force; it is a test to which these findings may be legitimately subjected, for if they indicate the workings of the primitive level of the mind then these savage customs should come into agreement with them. Such an identity Róheim claims to find throughout, a good example being the nescience of certain tribes concerning the relation between sexual intercourse and procreation. He shows that the knowledge of this relation manifests itself in beliefs and rites which express infantile sex theories already familiar in psycho-analytical work. This example is one out of many, but not all are so easy to understand. In the deductions the writer draws as to the distribution of the proto-Australians and later immigrants, he is in accord with other authorities. A more limited thesis, however, would probably have a better chance of acceptance by ethnologists. The book is a product of a close study of the literature and is provided with extensive references.

THE CONTROL OF THE BREATH.

An Elementary Manual for Singers and Speakers. By GEORGE DODDS, Mus.B. Dunelm, and JAMES DUNLOP LICKEY, M.D. London: Humphrey Milford, Oxford University Press. 1925. Pp. 65 + xii. 6*s*.

THIS little manual gives, in simple language, a clear and readable description of the structure and mode of action of the respiratory mechanism, and, though much less fully, of the production of tone in the larynx. Little is said of the mechanism by which pitch is varied, and the vexed subject of vocal registers is not mentioned. The last third of the book is devoted to breathing and vocal exercises designed to obtaining control of voice and breath. The authors rightly believe that a knowledge of the mechanisms concerned is useful and not harmful to students of singing and elocution; to such this little book, with its excellent explanatory illustrations, will be helpful.

OLD DERBY PORCELAIN AND ITS ARTISTIC WORKMEN.

By FRANK HURLBUTT. London: T. Werner Laurie, Ltd. 1925. Pp. 312. 18*s*.

THIS book is admirably printed in brown ink and with wide margins. It appears that the format was selected as an attempt to get off "the Kelmscott track," but it does not seem to require any more justification than its comeliness.

Old Derby porcelain has an interesting history which is well set out, one of the most striking points in it being that, according to the author, the Derby factory was the only early English porcelain factory which, except for a few individual pieces, produced original ceramic statuary, giving regular employment to modellers on the premises. A chapter on figure-makers for reproduction is full of detailed information of the sort that the collector of china should have whatever his favourite brand, and the same may be said for the sections dealing with the painters of the figure and flower subjects, the birds, and the fruits on old Derby porcelain. All these chapters should be read in connexion with the latter part of the book, which consists of 59 plates illustrating the beautiful art and craftsmanship of various painters. One need not be a virtuoso in any way to admire these lovely little pictures, and persons who have never bought a pot or a plate in their lives—to say nothing of the more elaborate pieces—must often have felt curiosity about the painters, while to collectors the precise histories will be valuable and entertaining. As it is in the author's knowledge that many of our profession fall into this category, we do them a service in bringing this volume to their attention.

---

Reports and Analytical Records.

BRUSSON'S GLUTEN BREAD.

(BRUSSON, JEUNE AND CO., 311, GRAY'S INN-ROAD, W.C. 1.)

THIS preparation is sold in the form of rolls, each contained in a separate wrapper, and weighing about 1 oz. The rolls are extremely light, and consequently bulky in appearance. When analysed the following results were obtained :—

Moisture	12·5 per cent.
Ash	0·6 ,,
Fat	1·3 ,,
Protein	36·8 ,,
Starch and dextrin	42·7 ,,
Undetermined matter, fibre, &c.	6·1 ,,
	100·0
Matter soluble in cold water	12·4 per cent.

For purposes of comparison it may be noted that ordinary household bread, with a moisture adjusted to 12·5 per cent., contains 9·7 per cent. of protein and 73 per cent. of starch and dextrin. The Brusson bread is thus much richer in protein and poorer in starch and dextrin.

Formerly an almost complete absence, or at least a very marked reduction, of carbohydrates was considered an essential characteristic of a true "diabetic" food. Whilst a diminution of the carbohydrates in the diet of the diabetic is still deemed necessary, modern practice allows a somewhat more liberal use of carbohydrates than in the past, and under certain conditions some practitioners of recognised authority even permit, for a limited period, foods of high carbohydrate content, such as oatmeal, potatoes, and rice.

CLUBLAND WHITE PORT.

(T. R. PARKINGTON AND CO., LTD., 161, NEW BOND-STREET, W.1.)

When analysed this wine gave the following results :—

Present gravity	1·0161
Alcohol per cent. by volume	21
Total extractives	10·5 per cent.
Consisting of—	
Sugar	9·05 ,,
Total acidity as tartaric acid	0·36 ,,
Volatile acidity as acetic acid	0·03 ,,

These analytical figures are characteristic of a good port. The wine itself is of a "full character," well matured, soft to the palate, and with an agreeable bouquet.

(1) CIBALGIN ; (2) AGOMENSIN AND SISTOMENSIN ; (3) CORAMINE.

(CLAYTON ANILINE CO., LTD., 68½, UPPER THAMES-ST., E.C. 4.)

(1) Cibalgin presents in combination the analgesic and antipyretic properties of amidopyrin, a small dose of dial having been introduced for its sedative properties. It is, however, primarily intended as a non-narcotic analgesic. The manufacturers state that extensive pharmaceutical and clinical tests have confirmed the value of the compound as rapidly relieving pain without conducing to the formation of habit. The drug is available in the form of tablets and liquid for oral use, while ampoules are supplied for hypodermic injections.

(2) A claim was made recently, which has received support on the continent, that two active principles isolated from bovine corpora lutea may be used for the regulation of menstruation. These active principles or hormones have been termed Agomensin and Sistomensin, the first of which is recommended in cases of delayed menstruation, and the second in conditions accompanied by an over-profuse flow. Agomensin is of value in retarded menstrual flow occurring during an expected period or following a too scanty menstrual flow. Sistomensin appears from clinical results to act as a stabiliser of menstruation in cases of hyper-function, its use, therefore, being indicated in dysmenorrhœa and menorrhagia. With regard to both preparations interesting cases can be quoted from French and German medical literature, and considering the frequently obstinate nature of the symptoms to be relieved, and their prevalence in such varied associations, both drugs might well be given trial under carefully observed medical conditions.

(3) Coramine is the trade name for pyridine-β-carbonic acid diethylamide, which was the subject of an article by Prof. E. Stanton Faust published in THE LANCET of June 27th, 1925. This new synthetic chemical possesses a distinctive camphor-like action, and for many years unsuccessful attempts have been made to produce a water-soluble form of camphor having the typical therapeutic properties associated with the drug. Prof. Faust seems to have demonstrated that the action of Coramine is almost identical with that of camphor, and, indeed, superior in its action on the heart. According to him, in small doses it exhibits an effect similar to that of digitalis, while its stimulating effect extends to both the motor and sensory nervous systems. Coramine should be, therefore, indicated in such conditions as heart asthenia following infectious diseases, the appropriate renal affections, poisoning through narcotics, and asphyxia of the new born, and records of such cases and of cases of bronchial asthma and emphysema are reported where its use has been efficacious. The drug is available in the form of liquid for oral use and in ampoules for parenteral administration.

OPOIDINE.

(J. F. MACFARLAN AND CO., EDINBURGH AND LONDON.)

Towards the end of 1922 we noticed Opoidine favourably as an example of a mixture of the total alkaloids of opium in soluble form. The drug contains about 50 per cent of morphine, the remaining 50 per cent. consisting of other opium alkaloids, concerning the latter of which there is evidence that they are of value in particular directions. Messrs. J. F. Macfarlan and Co. have now introduced a solution of opoidine in combination with scopolamine in ampoules, and they have received evidence of the value of the combination, one practitioner writing in respect of the production of "twilight sleep," stating that he has obtained in a certain number of cases complete amnesia after the first dose of the combination.

CAPROKOL (HEXYL RESORCINOL B.D.H.).

(THE BRITISH DRUG HOUSES, LTD., 16–30, GRAHAM-STREET, CITY-ROAD, N. 1.)

Caprokol is a new urinary antiseptic synthetic remedy for oral administration. It was first brought to the attention of the medical profession at the annual meeting of the American Medical Association last year, when Dr. Veader Leonard, of Johns Hopkins University, gave a description of work carried on at his department of bacteriology over a series of years on the alkyl resorcinols. These are claimed to be more powerfully germicidal than any other known class of substances of equally low toxicity. Clinical reports published on the introduction of hexyl resorcinol and others since received indicate that it possesses valuable properties, in that it is chemically stable, non-toxic, and non-irritating to the urinary tract, and administrable by the mouth. The reports submitted to us go to show that Caprokol exhibits a powerful antiseptic action in high dilution in urine of any reaction, while its elimination in the urine has a local antiseptic influence. A short series of cases of urinary tract infections treated with Caprokol is published under Dr. Leonard's authority, and indicates that many obstinate cases hitherto resistant to treatment had lost their symptoms under use of the drug. Reference to the discovery and properties of hexyl resorcinol have already appeared in THE LANCET, and we comment this week in an annotation upon the results obtained by Dr. R. B. Henline through the employment of this urinary antiseptic.

Iodosal is the correct name of the "supertonic table salt" supplied by Messrs. Francis Newbery and Son and noticed in this column on Oct. 24th.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 7, 1925.

STATUTORY DENTAL BENEFIT.

THOSE who have read the evidence submitted to the Royal Commission on the National Health Insurance Act, during the investigation which is now drawing to a close, must have been struck by the unanimity with which all sorts and conditions of witnesses testified to the desirability of making dental treatment a statutory benefit under an amended Act. Long before the evidence given by the various dental societies was reached, representatives of approved societies were paying generous tribute to the good which had resulted from the partial dental treatment at present given as an additional benefit, paid for to a certain limited degree out of the funds released under the first valuation, and were advocating its conversion into a statutory benefit. Many of the witnesses, indeed, were so convinced of the necessity for this that they recommended a partial pooling of their future surplus funds in order that all insured persons might benefit from the treatment. The members of the Commission, also, by their questions showed that they appreciated the desirability of extending the incidence of dental treatment over at least the whole of the present insured population. The case for making dental treatment a statutory benefit is, in fact, proved to the hilt. There remain, however, certain questions concerning which no unanimity exists—for example, the extent to which it is possible or desirable to make statutory dental benefit complete in the near future, and the manner in which such benefit as may be decided upon is to be administered. To give complete dental treatment will require, annually, a large sum of money, and if an increase in the present contribution be excluded as a possible source of supply, as indeed seems necessary in the financial state of the country, the money required can only be got by some rearrangement of the manner in which the funds obtained from the present contribution are spent. It seems evident that some such rearrangement will be made, but there are certain payments in connexion with medical treatment which have a first claim on any such funds, and it is doubtful whether what will be left when these claims are satisfied, even were it devoted entirely to the payment of the cost of dental treatment, would be sufficient. It may be assumed, therefore, that those schemes of complete dental treatment, not only for insured persons but also for their dependants, which were put forward by the dental and certain other witnesses, must be taken as ideals which cannot be realised as a result of the present inquiry, but towards the ultimate realisation of which it may be possible to take a very definite step. It is questionable whether any responsible dental authority, fully acquainted with all the circumstances of the present position, would desire to see complete dental treatment given as a statutory benefit at the present time, and it would seem from a careful reading of their evidence that the dental witnesses rather contemplate—between the realisation of such an ideal and the present chaotic condition of dental treatment as additional benefit—the prudent intermediate stage of a statutory dental benefit partial in its scope and limited in its time of application, which would afford the knowledge, not available at present, on which an effective and complete scheme of national dental treatment might be based.

There was agreement on the part of all the witnesses before the Commission that, for the present at least, payment of the dentist should be for services actually rendered on an agreed scale of fees and not by a capitation fee. One reason for this proposed difference from medical benefit is that it is quite impossible at present to estimate with any approach to exactitude the numbers of insured persons who would take advantage of dental treatment were it offered to them on terms similar to those under which medical benefit is given. Comparatively little can be learned from the experience of dental treatment as additional benefit, for there are many circumstances which tend to restrict applications on the part of insured persons for this treatment at the present time. Only members of certain approved societies fortunate enough to have surplus funds and which have adopted dental benefit are eligible. The formalities necessary in claiming the benefit and the fact that only about 25 per cent. of the dentist's fee is paid by the societies have also tended to keep down the number of persons obtaining the benefit. In one society consisting of women of a class likely to appreciate and to desire dental treatment, where every possible effort was made to bring the treatment under the notice of the members and to induce them to accept it, and where special means were available to assist those who had difficulty in finding a proportion of the fee, the claims all over the society did not exceed 12 per cent. of the membership. No dental witness contemplated a demand approaching 12 per cent. of the number of insured persons, and, indeed, were that proportion of claims to be expected, at the average expense per case which has ruled during the last five years under additional benefit, the cost of dental treatment would in the near future be prohibitive. Instead of making payment for any statutory dental benefit a first charge on the available contributions as in the case of medical benefit and making payment of the dentist by a capitation fee, the trend of the evidence given seems to point to the setting aside of a definite sum of an agreed fraction of a penny from the weekly contribution which, with the appropriate Government grant, would form a central fund or pool from which the cost of a certain definite amount of dental benefit for every insured person claiming it would be defrayed. There were various ways suggested whereby the treatment provided could be limited in accordance with the money available, as, for example, by giving free operative treatment, and, in addition, paying a proportion of the cost of any necessary dentures, the patient being left to find the remainder. Assuming a demand of 6 per cent., it was calculated that this amount of treatment would cost 3*s.* 3*d.* per annum per head of the insured population, and would leave the patient to find approximately one-third of the cost. The actuary of the British Dental Association submitted a modification of this scheme which would reduce the cost to a little below 3*s.*, an amount which would be covered by a payment of 0·58*d.* per member out of the weekly contribution with the corresponding State grant added. This approximates to the ½*d.* per week suggested by the representatives of one of the approved societies and indicates a feasible beginning. The professional evidence shows that practically everything in connexion with this matter of cost of dental treatment can be calculated with a fair degree of accuracy except the possible demand; but that is the crux of the problem, and it can only be satisfactorily solved by experiment on a large scale.

Faced with the problem of how to provide as much of a desired benefit as possible, the Commissioners naturally showed a tendency to explore what appeared to be attractive avenues of economical administration, and the relative merits of "panel" and "clinic" service took up no little time when the dental witnesses attended. Here a number of the dental witnesses showed to some disadvantage. The interests of the dental profession are undoubtedly necessary considerations, but if no more potent arguments against the establishment of whole-time dental clinics can be adduced, it is to be feared that the public interest must prevail. On the other hand, undue emphasis should not be laid on the success of such clinics where they are obviously the most suitable means which can be employed, as, for example, in the dental treatment of elementary school-children or in similar treatment at maternity and child welfare centres. These are special cases which have nothing necessarily in common with the dental treatment of adults as part of an insurance scheme. The feeling of the dental profession is at present opposed to the setting up of whole-time dental clinics. There is no certain knowledge that they would provide more efficient or economical dental treatment for the industrial classes than the 10,000 private practitioners who are able and willing to give it and who have voluntarily organised themselves for the purpose. Clinics cannot be a success unless they are established with the hearty support of the dental profession, and common sense appears to favour a continuance of the panel system in dentistry as in medicine in the immediate future. The methods of control at present applied to medical benefit could be easily duplicated or modified to suit the requirements of dental benefit. On the whole it would seem from a dispassionate review of the evidence given before the Commission that it would be a matter of legitimate surprise and regret should there not emerge in the report of the Commission a strong recommendation for the early institution of a definite measure of dental treatment as a statutory benefit under an amended Act. Without imposing further contributions on the already heavily burdened employer or employee this would soon effect such a reduction of the cost of sickness benefit as to liberate funds for the completion of the scheme.

SUBACUTE INFECTIVE ENDOCARDITIS.

NOT much was heard of subacute infective endocarditis till the latter part of the war and since. It was known as something of a rarity, but its symptoms were not understood and its differentiation from other similar conditions was not clear. Since the war it has become a commonplace and many observers have described and attempted to explain it. This increasing prevalence might be due either to more acute diagnosis or to the fact that very large numbers of men were sifted through more or less efficient filters or to some actual ætiological relation between war conditions and the disease. This last alternative seems to receive most support, and the apparently marked decline in the prevalence of the disorder during the last two years is giving another reason for believing that the war had a large share in causing it. The condition appears to be essentially a chronic bacterial poisoning, and its fatality is due at least as much to this as to the mechanical interference with the circulation produced by the valvular lesion. Its fatality, too, is extraordinarily high; with a few doubtful exceptions every case which has been definitely diagnosed has died within a period between a few months and two or three years. An inevitably fatal issue is extremely rare in parasitic diseases, and its occurrence in subacute infective endocarditis may mean only that diagnosis has not yet advanced beyond the point of being able to recognise the beginning of the end. No form of treatment has proved of any value. Any new information about it is therefore welcome, and there is much of interest in a paper on some of its bacteriological aspects in the current number of the *Journal of Pathology and Bacteriology* by Dr. H. D. WRIGHT, who has worked at it at University College Hospital in conjunction with Sir THOMAS LEWIS and his colleagues in the cardiographic clinic, where the clinical aspects have been thoroughly investigated.

It has puzzled many people that it should be so difficult to isolate organisms from the blood in a condition which is so obviously symptomatically a mild septicæmia, especially as the heart valves are the chief—indeed the only known—focus of the non-hæmolytic streptococci which are always obtained if anything is. The proportion of positive blood cultures has varied widely with different observers. In America it has been 70 per cent. or more, though LIBMAN has noted that they are not so easy to get now as they used to be. In Germany some workers report positive cultures in almost every case, while another group get figures round about 30 per cent., which is similar to the English experience. Dr. WRIGHT addresses himself particularly to the obvious proposition that negative results are due to imperfect technique. He points out that repeated examinations of the same case practically always give the same result, either positive or negative, and that there is no difficulty in isolating streptococci over and over again from a blood in which they occur in very small numbers. He adds to this a variety of experiments on media and methods, and comes definitely to the conclusion that the failure of a reasonably competent worker to isolate the cocci means that they are not there. Turning to the question of how and where the organisms live in the body, he points out that one is here confronted with very serious technical difficulties. Patients dying from a subacute endocarditis may suffer from a terminal invasion by other organisms, and if this does not occur during life a general spread of non-hæmolytic streptococci through the blood occurs so commonly after death that it is impossible with ordinary post-mortem material to get any certain and satisfactory information about the distribution of the causative organisms in the various tissues and organs. The cocci obtained from the blood during life, and to which the patients produce antibodies, are not demonstrably different from those which may be found in the blood post mortem in about a third of random autopsies. And it follows from this that agonal and post-mortem cultures are quite unreliable.

How this obstacle is to be surmounted is not at all clear; till it is we must remain in ignorance of whether the valves are really the main location of the cocci or whether they live somewhere else without producing recognisable anatomical lesions. Histologically, cocci can be readily stained and seen in the valvular lesions in cases where blood cultures have been positive. Where they have been negative cocci are sometimes easily found microscopically, but generally a finely granular material is alone present which might well pass for degenerated organisms or their dead remains, and is so interpreted by Dr. Wright. His careful observations by no means solve the problem of the disease, but they help considerably to define it. Clinically it appears to make little difference whether a case shows septicæmia or not, though a good deal of fever is more often associated with a positive blood culture than not. The cocci seem to live in the recesses of the fibrosing thrombi on the heart valves whence something or somethings emerge which stimulate the production of specific antibodies and kill the patient. Mair has produced an apparently analogous state in rabbits with pneumococci, and it is perhaps along experimental lines that the solution is to be expected. Meanwhile, it is satisfactory to note a diminution in the prevalence of a disease in which therapy is helpless.

THE CAMERON PRIZE LECTURES.

The third of the Cameron Prize Lectures is published in our columns to-day, completing an interesting series dealing with various conditions in relation to brain surgery. The lectures were prefaced on their delivery by a brief statement from the orator, Prof. Harvey Cushing, in which he pointed out that everyday symptomatic treatment of patients was, at least in the American medical schools, neglected in the curriculum, the expansion of scientific methods having somewhat crowded the art of medicine to the back of the stage. Prof. Cushing acknowledged the fascination of modern laboratory procedures for both the teacher and the taught; they lead to diagnosis and indicate treatment along the right lines of progression, but for many of the pathological conditions thus exactly discovered there is as yet no specific remedy, and we shall all agree with him in his suggestion that "more emphasis is laid in our schools on the methods of finding out what is wrong than on what should be done for it when it happens to be found." This was, presumably, the exact frame of mind which Dr. Andrew Robertson Cameron, of Richmond, New South Wales, was displaying when he founded the Cameron Prize in 1878 with a bequest of £2000 to the University of Edinburgh for certain specified purposes. We know little beyond what Prof. Cushing was able to tell us of Cameron himself. The son of a Tarland farmer, he began his medical studies at Marischal College, Aberdeen, migrating in 1859 to Edinburgh, where for his graduation thesis in 1861 he took the subject of "the corporeal sympathies of certain mental conditions"—a remarkably modern theme in all its relations. He went to Australia to practise his profession and died there some fifteen years later. Prof. Cushing imagines that, pitch-forked into a new country and unable to fall back upon consultant advice for therapeutic suggestions, he determined that practical therapeutics should be emphasised at Edinburgh so far as an endowed lectureship could bring this about, and the object he had in view was as shrewd a look into the future as was the subject he chose for his graduation thesis. For more than ever the young man who goes out to practise, versed in the lore of modern medical science and perhaps considerably expert in the advanced work of the laboratory, is at a loss when confronted with the sick. The regulations governing the award of the prize were remodelled by the Educational Endowments (Scotland) Commission, with the result that the proceeds of Cameron's bequest are now awarded annually to a selected person who in the course of the five years immediately preceding has made any highly important addition to practical therapeutics, and the Senatus of the University is entitled to request, as a condition precedent, that the chosen prizeman should deliver a lecture or course of lectures giving an account of his particular contribution to the practical side of medicine. Prof. Cushing decided to give an account of the recent developments of cerebral surgery in different directions, and dedicated his lectures to a long list of his collaborators, including those successively appointed at the Johns Hopkins Medical School, Baltimore, and the Arthur Tracey Cabot Fellows since 1912 whose function it is to take charge of the Research Laboratory at Harvard. To this group he added his resident assistants both in Baltimore and Boston, making an important category of men who have contributed greatly to the progress of neurology and surgery, and in associating their names with his lectures he insisted modestly that his own position as a Cameron Prizeman was due to a generous stretching of the conditions in his favour, his activities having been mainly in the direction of the teaching from which the notable contributions of his pupils was derived. But no such apologetic words were necessary for, apart from the value of Prof. Cushing's personal work, his centrifugal influence as a teacher has been and is of supreme importance. The name of Cushing rightly finds a place in the list of Cameron Prizemen, which includes Pasteur and Lister, Ferrier and Horsley, David Bruce, Manson and Ross, Finsen, Bier, Ehrlich, Flexner, and many other pioneers of medicine.

THE HEALTH OF THE NAVY.

For 85 years the Admiralty published an uninterrupted series of annual reports on the health of the Navy. The sequence was concluded in 1922 by the belated issue of a report for 1915, and it was then decided to allow the intervening years 1916–1920 to go by the board and to begin a new series of statistics with the report for 1921. The figures for that year have already been summarised in The Lancet,[1] and in the table on p. 987 of this issue they are compared with those for 1922, which are now available. The result is interesting. It would, of course, be rash to base much argument on the differences between two consecutive years, but for what they are worth the figures are encouraging. In 1922 deaths and accidents diminished in number; fewer men were invalided out of the service, and the daily sick-list was smaller. The total naval establishment fell from about 116,000 in 1921 to a little more than 100,000 in 1922. About half was allotted to the Home Station and a quarter each to the Atlantic Fleet and the fleets abroad. The death-rate was 4·4 per 1000 in the fleets abroad and 2·7 on the Home Station, and the most fatal single disease was tuberculosis, from which there were 36 deaths.

The incidence of tuberculosis for the Atlantic Fleet was 2·2 per 1000, and it is interesting to note that whilst marines at headquarters had a liability of 1·16 per 1000, the figure for those at sea was 1·57; the sick-berth staff had a liability of 3·18 per 1000, which represented an improvement. In general it is remarkable that the amount of tubercle in a population of young strong men, well clothed, well fed, and well housed, should remain the same in spite of every effort. The naval figures for venereal disease are particularly useful for they distinguish first infections from others. In this report they reflect the general diminution in syphilis without corresponding decrease in gonorrhœa. The fact that the numbers of fresh gonococcal infections per 1000 were respectively 60, 85, and 46 in the Atlantic Fleets, the fleets abroad, and amongst the men on the Home Station, suggests that the vaunted prophylactic methods in use in the Navy are not really effective. In the opinion of the medical officers the victims are apt to be intoxicated and too careless to use them. At any rate, these figures are very high. During 1922, 178 men were discharged on account of gonorrhœa, and there seem to be some grounds for the opinion recently expressed by a correspondent in our columns[2] that the civil authorities should take steps to prevent uncured cases returning without restriction to civil life.

Annotations.

"Ne quid nimis."

THE MEMBERSHIP OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON.

LAST August we drew attention to the fact that the Royal College of Physicians had lowered the age both for the examination for the Membership and for the conferment of the diploma from 25 years to 23. In the recent October examination 7 candidates out of a total of 53 availed themselves of this relaxation. At a Comitia of the College held on Oct. 29th, which is reported in our columns, a number of further changes were made, and as they are all in the direction of increased facilities for candidates, they will come into force at once. One provision is expressly designed to meet the case of medical men who have been engaged in special branches of practice lying outside ordinary clinical medicine. Such candidates, if over 30 years of age, may now submit work that they have published in any branch of medical science or in general literature, and if the Censors' Board decide that it is of sufficient merit they may excuse the candidate part or the whole of the examination. Another concession permits a referred candidate, in the absence of any special prohibition by the Censors' Board, to submit himself for re-examination without waiting for the expiration of six months, as hitherto has been the case. The revised regulations may be obtained on application to the Registrar at the Royal College of Physicians.

DEFECTIVE ILLUMINATION IN RELATION TO EYESIGHT.

A BULLETIN has been issued by the United States Public Health Service[1] which purports to prove by means of statistics that there is a definite relation between eye disease and the amount of illumination with which the workers are supplied. It was found that the employees at an old post office, the majority of whom were working under an average illumination of 2 to 3-foot candles, had a smaller percentage of normal vision and a greater percentage of certain eye defects than the employees at the new post office, the great majority of whom were working under all or part-time daylight. Hardly anyone would question the bad effect of straining the eyesight with poor illumination in causing fatigue of the eyes. Such fatigue may and does favour the advance of certain diseases of the eye, both superficial and deep, and certain tendencies such as a predisposition to myopia when these are already present. But to maintain that fatigue of the eyes by itself is capable of initiating disease of the eyes on a large scale—the contention of the bulletin to which we have referred—is to maintain something that is inherently improbable and of which no sort of proof is offered. When we examine the details of the statistics on which the argument is based, the fallacy becomes manifest. By far the greater proportion of the "eye diseases and defects" found in the two post offices consisted of errors of refraction and cases of "muscular unbalance." Cases of myopia which might conceivably have been due to defective illumination were hardly as a matter of fact of more frequent occurrence in the badly-lit post office than in the well-lit one. The excess of the cases of defects of the eyes in the former was due, to a small extent to hypermetropia, a condition which may exist without producing any symptoms except a liability of the eyes to be easily fatigued; to conjunctivitis, a condition due to infection, but which is undoubtedly favoured by fatigue of the eyes; but chiefly to muscular unbalance and especially exophoria, which is in no sense a disease and hardly a defect of the eyes, but is a condition which only produces symptoms when the eyes are used for long periods of convergence on near work. The balance excess of cases of defective eyesight in the badly-lit post office was mainly due to "asthenopia," a word which, if it does not mean fatigue of the eyes, means nothing. To sum up, we find no evidence that defective illumination is in itself a cause of permanent injury to the eyesight, except possibly in cases where myopia is either potentially or actually present, and in cases where there is a tendency to inflammation either of the conjunctiva or of the deeper structures of the eye. On the other hand, there is plenty of evidence of what common sense points to—that work for the eyes under defective illumination involves fatigue, and that this may cause permanent injury to "weak" eyes, and in any case is prejudicial to the efficiency of work performed under such conditions. The recommendations as to the lighting of public offices with which the bulletin concludes will be generally endorsed. These recommendations include direction not only for the provision of sufficient illumination but also for the avoidance of glare.

AN AUSTRALIAN HEALTH BULLETIN.

WE have recently received a copy of the second health bulletin issued by the Department of Public Health, Victoria, Australia. The bulletin is described as a quarterly journal issued under the direction of the Commission of Public Health for the information of councillors, medical officers of health, and health inspectors. The Commission is presided over by the Minister of Public Health, Dr. S. S. Argyle, and includes three other medical men among its eight members. Besides information about the prevalence of infectious diseases, records of new by-laws and reports, the bulletin contains well-written articles on carbon monoxide poisoning, heliotherapy, goitre, tuberculin testing of cattle, hydatids, plague, maternal mortality, infantile paralysis and cancer, and a "wireless talk" on the care of the children's teeth by Dr. O. Behrend, clinical demonstrator of the Australian College of Dentistry. Recent fatalities in bathrooms in Melbourne have drawn attention to the dangers of carbon monoxide poisoning, and some reference is made to its incidence among garage workers. In the article on goitre a description is given of the scheme which has been inaugurated for the prevention of goitre among schoolchildren in the Bairnsdale district of Gippsland. The method adopted is to give the children a dose of 2 gr. of iodide on each of ten consecutive days twice a year. No charge is apparently made for the bulletin and nothing is said as to the means of distribution, but we should imagine from the popular style of its language that this journal is likely to appeal to a much wider circle than the officials for whom it was originally intended. The issue of such authoritative bulletins by a Government health department would appear to be a very useful method of cultivating the health conscience.

HEXYL RESORCINOL: A URINARY ANTISEPTIC.

AN account of the discovery and properties of hexyl resorcinol was given in our columns[1] early this year, and it was then remarked that Veader Leonard's original communication[2] on its merits contained no detailed clinical results. We have now received a paper[3] by Roy B. Henline, of the Department of Urology of the New York Hospital, which describes his results in treating 50 cases of urinary tract infections and offers strong evidence of the value of hexyl resorcinol in practice. The claims that have been made for this drug are considerable. It is said to have all the qualifications necessary to the ideal urinary antiseptic—it is chemically stable, non-toxic, and non-irritant to the urinary tract; it is administered by the mouth and is mainly eliminated by the kidney, and it has an antiseptic action in high dilutions of urine of any reaction. Although there may be slight intestinal irritation or diuresis after the first few doses, these symptoms disappear promptly; in order to minimise gastric disturbance the drug is given in 25 per cent. solution in olive oil enclosed in a suitable gelatin capsule, and is administered immediately after meals. An excess dosage is necessary because the bulk of each dose is eliminated as a conjugate in the urine. The conjugated drug has no bactericidal action, and there is wide variation in different individuals in the amount required before the desired effect is obtained. Some will secrete bactericidal urine one hour after a small quantity has been given; on others large doses have no effect for three or four days. During the treatment, before disinfection is complete, the urine will still be a good culture medium; but after it has become sterile it will kill broth cultures of the organism originally responsible. To get good results the urine must be in contact with the infecting agent, and if the infection has penetrated the mucosa prompt disinfection cannot be expected. Treatment should be continued for at least two weeks after the urine has become sterile, and it is said that even in cases in which complete disinfection is not obtained there is often pronounced symptomatic improvement.

[1] The Hygienic Conditions of Illumination in Certain Post Offices, especially Relating to Visual Defects and Efficiency. Government Printing Office, Washington, D.C. 20 cents.

[1] THE LANCET, 1925, i., 448.
[2] Journal of Urology, 1924, xii., 585.
[3] Ibid., 1925, xiv., No. 2.

All the cases of pyelitis and cystitis in this series reported by Henline were thoroughly investigated before hexyl resorcinol was given. Each was subjected to a rigid physical examination and all possible foci of infection were removed. A complete cystoscopic examination was made in all the cases; cultures from the bladder and each kidney were taken, and the output of urea and phenolsulphonephthalein was estimated. The urine was, of course, carefully examined microscopically and chemically, pyelograms being taken in the sitting and dorsal positions. After all possible complications had been thus eliminated there remained a series of cases of chronic infection in which there was pus and positive bacterial cultures, and it was on this series that the treatment was tried. In the 26 cases of *B. coli* infection studied, the average duration of the disease was 3·67 years. Half of them had some definite urinary complication, such as prostatitis or renal calculus, and nearly all had been under treatment, which had included dilatation of the ureter and kidney, and pelvic lavage with 1 : 1000 neutral acriflavine at intervals of from one to four weeks. The average time of treatment before hexyl resorcinol was started was six months, and after the drug was given the urine of all the patients except two became sterile within 140 days. The average time before this occurred was 63·5 days. In the two failures the infection cleared up in the kidney or the bladder, but not in both, and there was one case of recurrence in a man who had to stop treatment prematurely. Each patient received 0·3 g. of the drug three times daily, and treatment by ureteral dilatations and kidney pelvic lavage with neutral acriflavine, 1 : 1000, at intervals of one to four weeks, was continued in addition. A few of the patients also had operations performed—e.g., nephrectomy—during the period described. In 12 cases of bladder and kidney infections caused by organisms other than *B. coli*, five were caused by staphylococcus, two by *Bacillus lactis aerogenes*, two by *B. proteus*, one by streptococcus, and two by mixed infections. The average duration of the disease from the history was two and a half years, and 75 per cent. had some complication. The average length of treatment by dilatation and lavage before hexyl resorcinol was used was nine months, and after it was administered the urine became sterile in 11 of the 12 cases within 133 days. (In the other case, which was clinically cured, *B. fluorescens* persisted.) On the average it was sterile in 50·7 days; and the average time required for staphylococcal infection was only 18 days. There were no recurrences.

In brief, therefore, in this series of 38 cases 92 per cent. were cured. Of the three failures, one did not return for treatment, one still had a growth of *B. fluorescens*, and one was complicated by a bladder tumour. All these three were clinically cured. In his conclusions Henline lays stress on the necessity for complete examination of the urinary tract before starting treatment, and states that hexyl resorcinol "is apparently superior to all other urinary antiseptics described." The duration of the disease, he says, seems to have no bearing on the length of time needed to effect a cure, provided that the renal parenchyma is undamaged. By thorough disinfection of the urinary tract hexyl resorcinol is an aid in preventing the recurrence of calculi, and in post-operative urological cases it is useful in healing wounds infected by streptococci. The remainder of Henline's series of over 50 cases were instances of gonococcal infection in the male. The number was not large, but no beneficial effects were recorded. We understand that hexyl resorcinol is at present being manufactured in this country by the British Drug Houses, Ltd.

SAFETY IN RADIOLOGICAL WORK.

NOT the least important subject discussed at the recent International Congress of Radiology held in London was the protection of workers exposed to radiation. The Physics Section drew attention to need for uniformity in protective methods throughout the world, and we learn from the organising committee of the Congress that the subject is likely to be discussed again at the next international meeting to be held in Stockholm next year. The British Institute of Radiology does well through its committee to insist on the importance of this matter. Some general basis of protective methods, which can easily be put into practice, is a necessity, not only in X ray and radium work, but also in heliotherapy. The increasing use of these methods makes it the more necessary that careful attention shall be given to securing healthy conditions for the personnel. When high-power carbon arc lamps are installed the ventilation of the premises is of the greatest importance, and the nursing staff must be protected from the glare of the lamps by efficient goggles, otherwise persistent headache and lassitude will soon make their appearance. An X ray and radium protection committee was formed in this country in 1921, and they have issued a number of valuable reports. No doubt the committee will in future include in their reports every form of radiation which is used therapeutically, and we look to them to keep the medical public acquainted with such methods as may be considered advisable. In no way does this diminish the necessity for international coöperation, but it is to be hoped that this country will continue to take a foremost place in devising methods of safety for those engaged in what, in default of such methods, is a dangerous occupation.

CYTOLOGY OF CANCER.

IN a recent issue of THE LANCET[1] attention was drawn to papers by Dr. R. J. Ludford and by Prof. A. Maximow dealing with cellular changes in test-tube cultures of normal tissues. These changes were so similar to those seen in cancer cells that they led Prof. Maximow to suggest the interesting possibility of having induced a cancerous transformation of normal mammary cells by his special conditions of cultivation. We then pointed out that the morphological changes described did not necessarily represent the essential character of malignancy; they might be merely the result of abnormal conditions of growth and nutrition. This criticism finds support in another paper on the General and Experimental Cytology of Cancer by Dr. Ludford,[2] which has just appeared. In this paper the author has reviewed and summarised the vast literature on the cytology of cancer and has supplemented it by original observations. Nothing is more tedious to read than verbal descriptions of morphological appearances. Dr. Ludford has avoided this difficulty by summarising observations and theories in the form of diagrams, either original or else constructed from the authors' figures drawn in a more diagrammatic manner than the originals. "This pictographic method has been adopted," as he states, "as being more precise and more compact than it is possible for merely verbal descriptions to be. It enables the reader to survey a wide field more easily and more rapidly than is possible in any other way." The paper of 40 pages, of which almost every second page is an illustration, has the charm of a picture-book and succeeds in condensing a vast amount of information in the clearest possible manner. Dr. Ludford's general conclusion is that present microscopic methods do not enable us to distinguish between a normal and a cancerous cell. The cancer virus of Gye and Barnard is too small to be seen with the microscope in common use at the present time. The wide range of pathological variations described in the past "are the morphological expression of the reaction of the cells to the peculiar conditions of tumour growth. There is no pathological state restricted to cancer cells alone, so that there exists for the cancer cell no precise morphological diagnostic character of any kind." The paper deserves to be read by every pathologist for its contents and to be imitated in its method of presentation.

POISONS IN THE HOME.

THE letter from Mr. Frank Briant, M.P., which recently appeared in the daily press, draws attention to a danger which is well known, but of which the magnitude is perhaps seldom realised. "On a shelf in practically every home," Mr. Briant writes, "lies a bottle the contents of which are capable of causing a violent and terrible death to the whole family." This bottle holding spirits of salt or some other domestic poison must, according to law, be a distinctive one; but it is fairly clear, Mr. Briant thinks, that in many cases the law is not adhered to. Harmless substitutes might be found for domestic uses—this is a matter he leaves to chemists. Meanwhile, the public should insist that these poisons be sold only to those who are capable of appreciating their dangers and should take infinite care over the disposal of the bottle on the shelf.

The general suggestions contained in Mr. Briant's letter seem eminently sound; the difficulty lies in their practical application. A tightening of the regulations with regard to the sale of poisons, ensuring that they should only be sold in fluted bottles, may accomplish something, but much would still depend upon the public themselves, and the real crux of the matter lies undoubtedly in the better education of the public in these matters. It is no use rigidly insisting on poisons being sold only in an easily recognisable bottle if the latter is then subsequently used for storing some harmless domestic fluid with the result that familiarity breeds contempt. It is only a public educated and trained to reasonable care in these matters that can be relied upon to be immune from poison casualties. In any case there is a good deal to be said for the suggestion that harmless substitutes might be found for domestic use. Poisons in the home are used chiefly for three purposes—namely, for cleaning, for disinfecting, and for exterminating vermin. Most of the accidents arise from poisons used in the first two categories. The use of crude hydrochloric acid, popularly known as "spirits of salt," naturally finds much favour for removing calcareous deposits, especially in districts with hard water-supply. Vinegar may be used to some extent as a substitute, but in amounts necessary to produce the same effect it is, of course, more costly, and a really satisfactory substitute for "spirits of salt" would be welcomed. Accidents arising from the use of disinfectants and antiseptics are usually due to some preparation of phenol or cresylic acid. Many less dangerous substitutes for these are to be found, foremost amongst them the majority of essential oils, many of which possess extremely high carbolic acid coefficients with relatively small toxicity to human beings. For example, the coefficient of oil of origanum is 26, thyme 15, clove 9, rosemary 6, lavender 5, and sandal-wood 1½. The high coefficient of oils such as origanum and thyme is readily understood in view of their high content of such powerful antiseptics as thymol and carvacrol, but the rather high coefficient of oils such as lavender and sandal-wood is surprising. These essential oils are, of course, more expensive than disinfectants derived from crude carbolic acid, but the cost of saponaceous solutions of the cheaper essential oils should not be prohibitive. Other comparatively innocuous antiseptics are to be found amongst oxidising agents such as hydrogen peroxide, sodium hypochlorite, and the organic chloramine derivatives. A number of proprietary antiseptics of low toxicity based on these substances are available at a reasonable cost. Accidents arising from the use of vermin killers are rare, for exterminators of the specific virus type are not poisonous to human beings.

THE CINEMA IN NEUROLOGY.

THE slow-motion cinematograph has gone far to prove that the sluggishness of man's reflexes cuts him off from a world where time moves leisurely and everything is more beautiful and more graceful than we recognise. Bacteriology has abolished the conception of dirt, and it may be that the cinema, *mirabile dictu*, will convince us that ugliness is a myth. In the meantime its possible applications to medicine have escaped the notice they deserve, and it is pleasant to note the work on bradykinetic analysis by the cinematograph which has been carried on during the past few years by Dr. Frederick Tilney and Dr. S. Philip Goodhart, professor of clinical neurology at Columbia University, New York. Working at the Montefiore Hospital and at the University they have prepared a series of films showing movements in nervous diseases, and on Oct. 23rd Dr. Goodhart gave a demonstration of his work at the Paris centre of the American University Union before a distinguished audience of neurologists. The films are the only ones at present in existence dealing (from the technical aspect) with nervous disease, and they include records and analyses of muscular movements in dystonia musculorum, encephalitis lethargica, chorea, progressive muscular dystrophy, and multiple sclerosis. There are records at the usual speed and at slow motion, and they have proved of value not only for undergraduate teaching, but for case records, verification of diagnosis, and follow-up work. The six reels shown illustrated the special uses of the method—namely, determination of the character of muscular movements; analysis of reflex movements; revelation of movements inappreciable by the naked eye; differentiation between functional or psychic and organic states; record for comparison with necropsy findings, and prognostic indications. It is found that a long, slow, progressive muscular wave appears in spasmodic movements occurring in encephalitis and seemingly in other conditions referable to lesions of the basal ganglia (thalamic and striate regions). Whether this peculiar movement is diagnostic of basal (striate) lesions is not yet certain, but if so, slow-motion analysis should be of special diagnostic value. Seemingly purposeless movements prove, on analysis, really of associative and symbolic character, showing emotive effects and a segmental nature. They express a psychic state, representing approach and retreat, entreaty and a negative feeling of shame. Slow-motion analysis shows the relation of symbolic and emotive movements to motor effects and reveals possible connexions between the corresponding sensory, or thalamic, and motor, or striate, lesions. Hysteria may thus have basal ganglionic relations. In all such conditions there is a suggestion of the effect of constant nervous stimuli in creating minute lesions, too fine for demonstration by present methods, which are at the basis of conditions now considered purely psychic or functional. In recording reflex movements it is found that in some states the patellar reflex, and possibly other reflexes, have a pendulum-like character, the limb continuing to oscillate for a number of times after the hammer blow. There is also a remarkable prolongation of the interval elapsing between the hammer blow and the first reflex response. Movements inappreciable to the naked eye exist in dystonia musculorum, and this fact is useful in diagnosis and prognosis since dystonia musculorum is incurable. Certain cases thought to be hysteria or dementia præcox have been found to be really cases of dystonia. Many other movements are well shown by the films—for instance, the champing and chewing movements often present in postencephalitic states, and a very interesting case is shown, in which, following grave fright produced by a violent thunderstorm, the patient presented movements initially of escape, or fleeing, and considered of psychic character. Slow-motion analysis showed the progressive muscular wave, so strongly suggestive of striate lesion, referred to above.

TYPHOID CARRIERS IN GLASGOW.

DURING Dr. A. K. Chalmers's last year of office as medical officer of health for Glasgow an investigation was carried out among the contacts of enteric fever patients to ascertain to what extent the source of infection might be attributed to carriers. The period covered was from Sept. 1st, 1922, to Sept. 30th, 1923. The investigation revealed that among 374 home-contacts of 102 patients only in eight instances was there bacteriological evidence of a similar infection. Further inquiries showed that four of these contacts were probably " missed " cases of a mild nature. Of the remaining four, three (all women) continue to be definite carriers and remain under supervision, two of them in the city and one in another district. None of them, however, take any part in the preparation of food. The fourth carrier, an ex-Service man, with a history of dyspepsia dating from military service, had large numbers of typhoid bacilli in his excreta. He was treated with autogenous vaccine and his fæces were found to be negative on two occasions a year later, when the dyspeptic symptoms had entirely disappeared. It is suggested that this investigation shows that the carrier is only responsible for the incidence of enteric infections to a very small extent. Three female carriers were admitted to Belvidere Hospital with a view to studying the best methods of curing the condition. No results were obtained by dietetic, antiseptic, and vaccine treatment, and only after excision of the gall-bladder were continuous negative findings obtained in two of the cases. The third case was detained for a much longer period, and finally left hospital of her own accord for her home in the north of Scotland. An example is given of a family infected by a carrier. On Nov. 17th, 1923, a child of 6 was notified as having enteric fever. He was one of a family of Russian Jews, numbering 11 persons, and including a grandmother aged 60. Ultimately the grandmother was found to be a carrier, as the result of a notification of a second child in June, 1924. In July two more children, aged 11 and 15, sickened, and in August the other inmates of the house were inoculated. No further cases have occurred. The family remain under supervision, and the grandmother is still a carrier.

HOSPITALS AND HEALTH CENTRES.

A LEADING article under this heading prefaces a special issue [1] of the *Architects' Journal* on Oct. 28th. The special issue is itself a sequel to a similar issue published by that journal in June of this year, and the two fully illustrated supplements comprise a valuable story of hospital construction. Both are well and profusely illustrated, and the text which accompanies them explains clearly such pertinent matters as the conversion of country mansions into special institutions and the heating, ventilation, cleansing, and flooring of hospitals. A section on modern American hospitals gives a series of typical ground plans and diagrams of new fittings ; there are several valuable suggestive notes and plans on the construction of nurses' homes. The leading article rightly suggests that while great central hospitals and special institutions, whose plans and elevations make up a large portion of the special issues, must be built with all the knowledge and skill which architects can provide to render them practical as well as comely, the great need of the immediate future may be the erection of smaller hospitals, sometimes as annexes to central institutions situated where further development is impossible, sometimes to meet the needs of growing communities, and sometimes to provide a focus of institutional treatment in rural areas. There is no doubt that this view of what will be required in the future is a sound one. The present shortage of hospital beds in the country has been estimated by the Voluntary Hospitals Commission at 10,000. The hospitals implied require building and will have to be built, not in order to realise either the dream of an architect or the ambition of a community, but for the needs of a public which will have to find a large share of the money.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comdr. C. R. Rickard is placed on the Retd. List with the rank of Surg.-Capt.

ROYAL NAVAL VOLUNTEER RESERVE.

Proby. Surg. Sub-Lt. E. I. Puddy to be Surg. Sub-Lt.

ROYAL ARMY MEDICAL CORPS.

Capt. J. G. Gill relinquishes the temp. rank of Maj. on ceasing to be empld. as Dep. Asst. Dir. of Hygiene and Pathology, N. Ireland District.

A. K. J. Finch to be temp. Lt.

ARMY RESERVE OF OFFICERS.

The undermentioned Colonels (late R.A.M.C.), having attained the age limit of liability to recall, cease to belong to the Res. of Off. : E. W. Bliss, T. H. M. Clarke, R. W. Clements, P. Evans, H. Hewetson, A. W. Hooper, A. E. C. Keble, C. B. Martin, G. A. Moore, F. S. Penny, H. V. Prynne, E. W. Slayter, G. St. C. Thom, H. S. Thurston, and C. W. Profeit.

SUPPLEMENTARY RESERVE OF OFFICERS.

Capt. J. R. S. McDowall, late R.A.M.C., T.A., to be Capt.

Capt. A. R. Balmain, late R.A.M.C., Spec. Res., to be Lt.

TERRITORIAL ARMY.

Maj. W. C. Gunn, from Sanitary Companies, to be Maj.

Capt. D. Mackie to be Maj.

Maj. A. W. Uloth, late R.A.M.C., to be Capt., and relinquishes the rank of Maj.

Sanitary Companies : Capt. A. Davidson to command the 5th (Scottish) Sanitary Company.

DEATHS IN THE SERVICES.

Capt. Thomas Barker Amyand Haggard, who died recently at the age of 50, was a graduate of Cambridge University, and studied medicine at St. Bartholomew's Hospital, where, after taking the Conjoint qualification in 1903, he acted as house surgeon. Later he was appointed house surgeon at the Victoria Hospital for Children, Chelsea, and clinical assistant at the Central London Ophthalmic Hospital. Capt. Haggard, who in 1907 married his cousin, a daughter of the late Sir Rider Haggard, quite recently retired from the Royal Army Medical Corps.

It has been officially announced that separation allowance will be granted to I.M.S. and R.A.M.C. officers when posted to stations such as Razmak, where their families are not allowed to accompany them. Allowances range from Rs.40 a month for lieutenants to Rs.340 for Deputy Directors of Medical Services.

A Fleet Order notifies that the loan of a surgeon commander R.N. is required by the Royal Australian Navy in exchange. The exchange is for two years and the officer must sail at an early date.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CXLVI.

THE TREATMENT OF BREAST ABSCESS.

While the typical breast abscess of lactation follows infection through a cracked nipple, there are several precursors and variations whose treatment falls under this general heading.

Milk Engorgement.

This is produced by the blocking of a duct or ducts with epithelial débris during lactation or by the sudden termination of breast-feeding. It may simulate breast abscess, and if unrelieved passes into it. The breast becomes swollen, tense, and painful, and the affected ducts present an irregular hardness without the presence of the central area of softening which indicates pus. This condition will be prevented if care is taken of the nipples (see the Treatment of Sore Nipples, The Lancet, 1924, ii., 1299), and suitable measures are used when lactation has to be terminated.

The breast should be supported by a thick pad of cotton-wool with a bandage passing beneath it and over the opposite shoulder. The nipple should be cleansed with pledgets of cotton-wool soaked in boric lotion, and the breast pump employed. Hot fomentations should be avoided, but lotio plumbi may give considerable relief. If the need for breast-feeding has ceased a belladonna plaster should be used, and the following additional steps taken to inhibit further lactation: drastic diminution of fluids, the administration of mist. alba m. and n., and if the breast is not too painful it should be firmly bandaged over layers of cotton-wool after evacuation with the breast pump.

Acute Puerperal Mastitis.

This condition is one in which the inflammation is spread through one or more lobes of the breast, and is the immediate precursor of breast abscess. Practically all cases arise from a crack or abrasion of the nipple. The breast shows all the signs of an acute inflammation and the general constitutional disturbances are very marked, while only the absence of an area of fluctuation or of a central softening distinguishes it from breast abscess proper. Until the latter diagnosis is made it should be treated energetically on the same lines as milk engorgement.

The following points should be noted. The abscess should not only be looked for in the area of greatest swelling in the breast substance, but also under the nipple, where one of the dilated ducts may be infected. The possibility of the pus tracking along the deep aspect of the breast must be borne in mind and increased prominence of the breast and pointing at the outer and lower margin watched for. In cases of doubt, if the constitutional symptoms are severe, an exploratory incision may be made. The incision should be planned as indicated in a subsequent paragraph. Even if pus is not found the congestion will be relieved and drainage provided in the pre-suppurative stage. The incision should be lightly packed with gauze soaked in flavine or acriflavine, or better still in an emulsion of equal parts of flavine and liquid paraffin.

Acute Puerperal Breast Abscess.

When this condition is diagnosed from consideration of the foregoing facts, extreme measures must be taken at once. No attempt should be made to treat the breast with fomentations, nor should any small incision be made under local anæsthesia. In order that the whole breast shall not become infected and subsequently fibrosed the affected lobes should be thoroughly opened up under a general anæsthetic.

Abscesses are most frequently found in the following situations: (1) under the areola, (2) deep to the nipple in one of the dilated ducts, (3) in the main secreting portion of the breast, (4) the "shirt button" abscess on the posterior surface.

(1) The subareolar abscess appears close to the nipple as a reddened area in which fluctuation can be readily detected. Usually the rest of the breast is unaffected. An incision should be made starting at the base of the nipple itself and extending radially from it over the centre of the affected area to the outer limit of the zone of induration. The incision should be deepened with the knife until pus is found, though in this area it is usually very superficial. The abscess cavity when completely opened up is mopped out and temporarily packed with gauze. On removing this packing careful inspection will show whether pus is welling up from a more deeply placed abscess.

(2) An abscess in a dilated duct deep to the nipple can be recognised by a markedly prominent and painful nipple surrounded by an inflammatory zone, in which deep œdema is present and possibly fluctuation. There may be a purulent discharge from the nipple. This type of abscess will extend outwards into the parenchyma unless opened. The treatment is the same as that of the subareolar type.

(3) The parenchymatous abscess has already been distinguished from acute puerperal mastitis. The skin over it is red and œdematous and the breast feels irregularly hard. This type of infection is commonest in the lower half of the gland, but a decision must be made as to which lobes are involved and the treatment varied accordingly. In the lower half of the gland an incision should be made commencing just within the areola and extending radially over the lobe in which fluctuation has been detected and ending at the periphery of the breast. The lobe should be fully opened, carrying the incision well into its substance; the finger should be introduced and any loculi in adjacent lobes containing pus sought for and opened. These are sure to communicate with the main abscess cavity in the lobe most affected, but unless the fibrous partitions are broken down satisfactory drainage will not be obtained. Care should be taken that a pocket of pus is not left unopened in the region of the nipple. A half-inch drainage-tube of red rubber, with thin walls and several side openings, should be placed in the incision emerging at the outer end, and the incision lightly packed with gauze soaked in flavine and paraffin emulsion. After 24 hours the wound should be dressed, the tube and packing removed, and the wound repacked. The packing should be changed daily. After two days it is best to discontinue the flavine packing and to substitute eusol or Dakin's solution. The wound should not be swabbed out; any débris or small sloughs are best removed by irrigation with saline or eusol at the time of repacking. This also makes the removal of the packing an easy and painless process. The packing itself should be done systematically, being gently laid in from end to end of the wound in long strips.

In the case of the upper half of the gland a completely radiating incision is not satisfactory. In the first place, it will be objected to by the patient; and secondly, it will not give dependent drainage. An incision 2 or 2½ in. in length should be made over the inner part of the most affected lobe, extending as before radially from the nipple. This should be placed so as to lie somewhat obliquely, so that an incision placed in the most adjacent part of the lower half of the breast may be made to communicate with it. The second incision need not be much more extensive than the first, and may be commenced outside the areola. The intervening bridge of breast tissue should be broken down with the finger, and a drainage-tube inserted from the lower incision. A smaller tube may be placed in the upper one, and both incisions packed as before.

Cases treated in this way will be found to clear up much more rapidly than those in which more conservative measures are employed. Under the eusol treatment the wounds granulate up very rapidly. As soon as the discharge has ceased to be purulent the packing may be safely left in for two days, though a daily dressing is more comfortable. When the granulations reach the surface a dressing of sterile vaseline spread on gauze is best.

(4) The "shirt button" abscess is recognised by marked prominence of the breast with but slight signs of inflammation in the gland itself. An area of fluctuation may be detected at the outer margin of the lower half of the gland. The best incision for opening this type of abscess is a semilunar one on the margin of the gland, and the pus will be found between the breast and the pectoral fascia. When it has been evacuated the finger should be inserted and a search made for the area of gland substance from which it has arisen. It may be possible to open this adequately from the deep surface; if not, a small radially placed incision should be made over the affected lobe and carried through to the posterior part of the breast. Tubes should be inserted in both incisions, but packing will only be of use in the anterior one. The tube on the posterior aspect of the breast should not be removed for four or five days, being taken out when the dressing is done, boiled, and replaced. At the end of that time it may be removed altogether or a smaller one inserted for a few days more.

The possibility of this being a retromammary abscess arising from caries of a rib or from an empyema must be borne in mind. In both cases the breast will be prominent, and one of these conditions should be suspected from the absence of signs in the breast itself. An abscess from caries of a rib is the more common condition, and must be inferred when examination of both the chest and the breast is negative. Both these abscesses will be beneath the pectoral fascia, and they tend to point a little further out towards the axilla.

The subacute mammary abscess must be mentioned in passing as there is often some difficulty in differentiating it from malignant disease. It presents an œdematous indurated condition of the skin, often with retraction of the nipple, which very closely resembles carcinoma of the breast. However, the length of history, the association with recent lactation, and the absence of a lump should help in the diagnosis. Enlarged axillary glands will be present in both conditions.

Galactocele.

This condition is the only form of chronic breast abscess within the scope of this article, and must be mentioned in conclusion. Tuberculous mastitis, gumma, and actinomycosis are pathological rarities. It is a condition of retention of milk in a dilated duct, together with a mild degree of infection. It may be readily recognised as a distinct elevation near the nipple produced by a round or pear-shaped tumour, in which fluctuation may be readily obtained. It is painless, and firm pressure may produce a spurt of milky fluid from the nipple. In long-standing cases caseation of the contents takes place. It should be excised when lactation is over, the usual radiating incision being employed.

J. BASIL HUME, F.R.C.S. Eng.,
Chief Assistant, Surgical Unit, St. Bartholomew's Hospital.

Messrs. Watson and Sons (Electro-Medical), Ltd., have devoted their Bulletin No. 73 to apparatus producing what is known as artificial sunlight. The description of apparatus is prefaced by some general remarks on the nature, properties and biological significance of the part of the spectrum dealt with. Heliotherapy in medicine has come to stay and there is now a wide choice in the apparatus available. The two chief sources of artificial sunlight are either mercury-vapour lamps supplemented by some source to compensate for the lack of the longer wave-length, or open arc lamps of the carbon or tungsten or tungsten-cored type. There is a wide selection described and illustrated in this bulletin, and purchasers will do well not to forget that the best protective goggles are cheapest in the end and should be purchased against their absorbing power. It is impossible to tell by naked-eye inspection what is a good goggle and the spectrograph is necessary for this purpose.

Special Articles.

PROCEEDINGS OF THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.*

(Continued from p. 829.)

THE evidence which is summarised below is the final instalment of the report of the proceedings prior to October. The Royal Commission resumed its proceedings recently, and has been hearing further official evidence.

The National Council of Agriculture.

(App. LXXXV.; Q. 21051–21217.)

The National Council of Agriculture for England, represented by Mr. James Donaldson and Mr. Denton Woodhead, is strongly opposed to the pooling of the surpluses of Approved Societies, on the ground that the persons engaged in agriculture and other rural occupations are as a class healthier than most other industrial classes. The witnesses reminded the Commission that agriculturists had objected from the outset to the flat rate of contribution, and they cited statements made on behalf of the Government in 1911 to the effect that Approved Societies would be allowed to use their own funds for their own members.

It was elicited from Mr. Woodhead in the course of examination that one reason why his Society had a good surplus was that, though a rural workers' society, they excluded unhealthy members in the country.

---

* In previous articles the proceedings of the Commission were reported under the following headings: Introductory Note; The Scope of the Insurance Scheme (see THE LANCET, Jan. 31st, pp. 247–8); The Provision of Medical Benefit (Feb. 7th, pp. 301–3; Feb. 14th, pp. 355–6; Feb. 21st, pp. 403–5); Financial Provisions of the Act (Feb. 28th, pp. 454–7); Medical Certification and the Regional Medical Staff (March 7th, pp. 508–9); The Approved Societies and the Money Benefits (March 14th, pp. 564–5; March 21st, pp. 623–4); Evidence of the Hearts of Oak Society (March 28th, pp. 677–9); Evidence of the National Conference of Industrial Assurance Approved Societies and of the Manchester Unity Approved Society (April 4th, pp. 731–3); Evidence of Independent Order of Rechabites, of Rational Association Friendly Society, and of Miners' Societies (April 11th, pp. 784–6); April 18th, p. 839; Evidence of Mr. Alban Gordon (April 18th, pp. 839–40); Evidence of Joint Committee of Approved Societies, of Stock Exchange and Lloyds' Health Insurance Societies, and of Group of Catholic Approved Societies (April 25th, pp. 889–91); Evidence of the National Insurance Beneficent Society (May 2nd, pp. 943–4); Evidence of the British Medical Association (May 9th, pp. 993–5); Evidence of the British Dental Association and other Dental Organisations (May 16th, pp. 1044–6); Evidence of the Insurance Committees (May 23rd, pp. 1097–8); Evidence of Various Approved Societies (May 30th, pp. 1135–6); Evidence of the British Medical Association (June 6th, pp. 1184–6; June 13th, pp. 1248–50; June 20th, pp. 1315–6); Evidence of other Medical Bodies (June 20th, p. 1316; June 27th, p. 1348); Individual Evidence (June 27th, p. 1348); Medical Services in the Factory, Ministry of Health Inquiry Room, Evidence of National Sailors' and Firemen's Union and of Loyal Order of Ancient Shepherds (July 4th, p. 36); Evidence of Friendly Societies' Medical Alliance, South Wales and Monmouthshire Alliance of Medical Aid Societies, Friendly Societies' Medical Officers' Union, Association of Approved Societies, Standing Committee of Scottish Insured Women, and Society of Medical Officers of Health (July 11th, pp. 86–8); Evidence of the British Hospitals Association, the Sheffield Joint Hospitals Council, and the Middlesex Hospital (July 25th, pp. 181–2); Evidence of Opticians' Associations (August 1st, pp. 224–6); Evidence of Council of British Ophthalmologists, of Ophthalmic Benefit Committee, of Chemists, and of Drug Store Proprietors (August 15th, pp. 348–50); Evidence of Chartered Society of Massage and Medical Gymnastics, of the Ivory Cross, of Scottish Panel Chemists, Practice among Highland Crofters, and of National Farmers' Union of Scotland (August 22nd, pp. 402–3); Evidence of Nursing and other Women's Organisations (Sept. 5th, pp. 519–20); Views of Trade-Unions, Evidence of Approved Societies (Sept. 19th, pp. 618–9); Evidence of Joint Tuberculosis Council, Cambridgeshire Tuberculosis After-Care Association, London County Council on Treatment of Tuberculosis, British Social Hygiene Council, and London Insurance Committee (Oct. 3rd, pp. 722–3); Evidence of Society of Apothecaries of London, East of Scotland Dentists' Panel, Association of Poor-law Unions, Association of Parish Councils of Scotland, and of Mr. W. J. Braithwaite (Oct. 17th, pp. 828–9).

References to the paragraphs in the printed statements issued as appendices to the reports of the oral evidence are given thus: "App. X. 69," and references to the oral evidence thus—Q. 1369.

Evidence as to Casual Employees of Councils.

(App. LXXXVIII. and Q. 21317–21394.)

Mr. J. H. Barnby, of the Stepney Borough Council, stated that the Council employed persons on Sundays for the cleansing of the streets. He claimed that, as this employment was purely casual and intermittent, the men should not be subject to deductions for National Health Insurance contributions.

It was suggested to the witness that although this was part-time employment it was to some extent regular, and other types of casual employment were pointed out as having a better claim for freedom from contributions. It was also made clear to him that there was nothing in the Act to prevent the Council paying the whole contribution if, as appeared, they were willing to do so.

Delay in Paying Sickness Benefit.

(App. XCVII. and Q. 22731–22837.)

Miss M. A. Hilbery, who had at one time been a sick visitor for the Prudential Approved Societies, gave evidence in which she suggested that sickness benefit was often withheld from insured persons for long periods, and that this resulted either in return to work before recovery or actual hardship in regard to obtaining food.

National Insurance Audit Department.

(App. CI. and Q. 23209–23289.)

Mr. W. A. Middleton, acting chief auditor, gave an account of the whole machinery of audit of the accounts of Approved Societies. He pointed out that an Interdepartmental Committee reported in 1912 in favour of the employment of a whole-time audit staff, and said that their recommendations had been followed.

The witness said that the auditors undertook a great deal of work not ordinarily falling within the scope of an auditor's duties, but that there was no precedent for the working of such an enormous scheme as that under the National Health Insurance Acts, and a great deal of assistance had to be rendered to the societies.

> Is it a fact that it is the smaller societies that cause you greater trouble in your audit than the larger societies?—There is no shadow of doubt about that. It is a question of part-time officials having these complicated Acts and regulations which are beyond their capacity—not beyond their zeal.

With regard to the falsification of claims for benefit, it was stated by way of illustration that sometimes the dates were altered on medical certificates in order to extend the benefit period, or such certificates were fabricated by copying a signature from a genuine certificate.

> Experience shows that there is a greater temptation to construct false maternity benefit claims because of the comparatively large sums obtainable thereby—many such cases are disclosed by discovery of a second claim purporting to be in a member's name following at too short an interval upon another in the same name, either or neither being genuine.

The cases of fraud or failure in Insurance Committees' accounts have been few in number, and the amounts involved comparatively small.

Chartered Accountants of Scotland.

(App. LXXIX. and Q. 20342–20534.)

The evidence given on behalf of this body by Mr. John Reid was to the effect that the system of auditing by whole-time officials involved long delays and was not in the best interests of the successful working of the system, and that the multitude of duties which the auditors undertook showed a good deal of confusion as between auditing proper and actual supervision or inspection.

It was suggested that the auditing of the accounts of societies, both on the State side and the voluntary side, should be entrusted to outside professional auditors.

Evidence from the Department of Economics, University of Cambridge.

(App. LXXVI. and Q. 19794–19899.)

Mr. Joseph L. Cohen, of the Department of Economics of Cambridge University, criticised the present scheme of benefits as being wholly inadequate, and he advocated an extension of benefits all round. He stated that he could find no definite principle behind the present rates of money benefits, which bore no relation to any significant fact in industrial life. He also stated that—

> Administration of insurance by the Approved Society combines all the faults and none of the virtues of insurance by industry or insurance by the State, or insurance by local authorities. It cannot claim the virtues of being a democratic form of organisation.

Mr. Cohen advocated a system of health insurance administered by the Minister of Health, the benefit being paid through the Post Office and employment exchanges with a State guarantee covering all emergencies in the life of a workman's family.

The Actuarial Basis of the Act.

(App. XCIV. and Q. 22252–22404.)

Mr. Walter Farris, secretary of the Loyal Hearts Friendly Society, questioned the necessity for the whole actuarial basis of the Act. He said :—

> Under the National Health Insurance Act, spread over the whole of the insured persons, there must always be a similar range of ages and liability and the cost of benefits must remain fairly constant and proportionate to the number of insured persons, because the general public is forced to come under the Act at the age of 16 years and at the age of 70 ceases to be entitled to sickness benefits.

The witness suggested that there was no object in accumulating enormous reserve funds for the benefit of a future generation, and he proposed that there should be a system by which Approved Societies should be given credit from year to year for the expected sickness of their members who are actually alive at the commencement of each year, instead of the present system, which credits societies at the commencement of membership with the present value of the expected sickness of the member during the whole of the years that the member is expected to live.

His proposals included provision for continuous sickness benefit, the abolition of the three days waiting period, and exemption from arrears. He estimated that there would be accumulations in about 30 years' time of a gigantic sum of £818,000,000, which would never be wanted. It was suggested to the witness in examination that the figure was much more likely to be £200,000,000.

> I want to know whether that trifling difference would make any change in your point of view with regard to the present system?—Even if I accepted that figure I should still contend that the system that I suggest would be far preferable and there would be greater benefits to the insured person.

Mr. Farris was reminded, with regard to reserves, that there was a process continually going on of eating up existing reserves and replacing them by new ones.

The Government Actuary's Evidence.

(App. LXXXVII. and Q. 21237–21316.)

Mr. Henry, the Deputy Government Actuary, gave evidence with regard to the 1922–23 valuations of Approved Societies. He said that, with the exception of the disablement experience of women—

> the cost of benefits has been much below the provision made for it, 38 per cent. of the surpluses being attributable to this source. It should, however, be pointed out that the cost of disablement benefit in the case of both men and women has been constantly rising during the four years. The relation of the average cost of the period to the corresponding "expectation" is not altogether, therefore, a satisfactory index to present and future conditions in regard to this benefit.

Roughly speaking, the surplus on the last valuation amounted to about three times as much as that in 1918, but the surplus consists to quite a material extent of monies carried forward from the earlier valuation.

Since 1922 the sickness experience has been more unfavourable and there has been a steady downward curve so far as surplus is concerned.

The estimated total surplus of Approved Societies on the results of the 1922–23 valuations, the last of which will be published in 1926, is about £42,000,000, of which, said Mr. Henry, £14,000,000 must be reserved, leaving £28,000,000 disposable, to which has to be added £8,000,000 from the earlier valuation. The total disposable surplus was thus estimated at £36,000,000, or about £7,000,000 a year, to be spent over five years.

THE HEALTH OF THE NAVY IN 1922.

THIS report[1] gives a satisfactory account of the health of the Navy in 1922. Compared with the preceding year, there were fewer cases of illness or accidents, fewer deaths, fewer invalidings, and fewer men daily on the sick list. The table appended shows the distribution of the casualties.

For some reason the 4300 marines at headquarters are separated off from the 96,560 other men in the Service who are called the Total Force. In 1922, as against 1921, there was a reduction of about 16,000 in the total naval establishment, which falls readily into three great groups—viz., the Atlantic Fleet, the fleets abroad, and the Home Station. The last accounts for about half the establishment and the other two for a quarter each. The men on the Home Station include recruits, men under training or in depôts, and those awaiting discharge. The death-rate was 4·4 per 1000 in the fleets abroad and 2·7 on the Home Station; there were 99 deaths from drowning (54 of them in ships lost), 36 from tuberculosis, 32 from injuries, 25 from pneumonia, 13 from diseases of the intestines (10 from appendicitis), 12 from influenza, and 11 from malignant disease. The invalidings were, in order of magnitude, as follows: For diseases of the eye, 348; diseases of the ear, 260; tubercle, 198; gonorrhœa, 178; organic heart disease, 146; deformities of the limbs, 135; and neurasthenia, 111. Only 24 were invalided for syphilis, but there were three times as many in an average year before the war. A very valuable table on pp. 14–18 shows the number invalided for each disease group in each year of age or service. Invalidings are most frequent between 21 and 23 years of age, and about the fourth or fifth year of service. Deformities of the limbs cause most discharges in the first year of service; eye diseases go on steadily all through; ear diseases have their maximum in the first five years; heart diseases in the first two years and again after men have re-engaged; and tubercle has a maximum in the first five years and again, like organic heart disease, after re-engagement. It would therefore seem to be acquired, in part, in the service period. At the higher ages more men are discharged for tubercle than for venereal disease.

HEALTH STATISTICS IN THE GROUPS, ROYAL NAVY, 1922.

Figures for 1921 are in italics, on the left of columns.

Per 1000 men.	Training establishment.		Atlantic Fleet.		Fleets abroad.		Home Station.		Total force.		Marines at headquarters.	
Number in group	*3,637*	2,293	*29,050*	27,200	*26,950*	27,750	*54,700*	41,610	*110,700*	96,560	*5,480*	4,300
Wounded or killed in action	—	—	*0·03*	0·03	*0·28*	—	*0·34*	0·02	*0·24*	0·02	*2·2*	1·62

Of the vaccinations on entry only 8 per cent. (136) were primary. In 1921 28 per cent. of the new entries had to be vaccinated for the first time, and it looks almost as though the public were vaccinating itself as it should, but secretly. The Army has ceased to publish these vaccination statistics since the war, and no appeal to its experience can be made for confirmation or contradiction. Diphtheria and enteric fever had only half the incidence of 1921. Influenza was chiefly prevalent on the Home Station and in the Atlantic Fleet, and there were 67 cases in the latter as against 35 in 1921. The percentage case-mortality was 0·48 in the Atlantic Fleet and 0·16 on the Home Station; no one died in the Mediterranean. There were two meningococcus infections, of which one was at Harwich, where there had been no case for two and a half years. The boy had not been on leave for six weeks, and the examination of 456 contacts did not reveal any carrier. The other case, just as mysterious, was in a battleship near Constantinople, and neither was followed by any other case. The percentage mortality of pneumonia was 12 on the Home Station, 10 in the Atlantic Fleet, and 3 in the Mediterranean, which suggests that it is not without good reason that elderly persons are sent to the Riviera in winter. Tubercle caused much the same loss in 1922 as in 1921. Marines at headquarters had a liability, 1·16 per 1000, and for marines in ships it rose to 1·57; this was, however, a great fall from that of 1921 (3·2). The sick-berth staff had a liability of 3·18, which was the lightest they have had for years. The naval figures for venereal diseases are particularly useful, for they distinguish first infections, and in 1922 the cases of soft chancre and syphilis have decreased. Gonorrhœa cases were as before, but it is noted that this disease disappeared at Gibraltar when all brothels were closed. Prophylactic measures do not prevent these diseases because, in the opinion of medical officers (pp. 42 and 67), the victims are apt to be intoxicated and too careless to use them. Two cases of encephalitis lethargica occurred, one at Oban and one in China, and there were also two cases of anthrax, each ascribed to a new shaving-brush. Great attention is being paid to dental repair, and a 17 per cent. fall since before the war in diseases of the digestive system may be the result. Malignant disease (16 cases) showed a slight decrease; alcoholism was also less; two cases of mild poisoning were due to men strenuously treating their own colds.

---

[1] Statistical Report of the Health of the Navy for the year 1922. Published by H.M. Stationery Office, London, 1925. Pp. 176. 6s.

We asked last year for more information about what happens to boys, to the cadets at Dartmouth, and to the younger men under training. If anything, rather less information is given. The tables are again rather inconsistent, in a manner unusual in Government publications, and those on pp. 170 and 91 do not bear comparison. Calculated on the figures of p. 170, pneumonia has greatly decreased, the rate being 3·5 per 1000, as against 12·3; there is no statement about tuberculosis. In the youths' training establishment the phenomenal death-rate of 23·52 per 1000 refers to two deaths only, but the fact that nearly one-third of the youths in the establishment (29) were invalided in five months, whilst only 16 were invalided from the *Ganges* in the whole year, seems to require explanation.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Posting of Food Prices in Paris.

ECONOMICAL buying of foods and other necessaries of life is as pressing a need to the housewife in Paris as it is in other great cities. A considerable difference exists in the prices demanded for identical articles in different parts of the city. The unduly high prices prevailing in quarters largely inhabited by wealthy foreigners are mostly due to carelessness in buying on the part of the householder, who leaves, without scrutiny, the purchase of food, fuel, and the like to servants, who, thus tempted, obtain illegitimate rebates and make unscrupulous bargains with the pettier merchants. Even dishonest bills are thus often presented to the householder, who fails to examine them and so permits the merchant and servant to divide unlawful profits. The prices of bread, milk, meat, eggs, butter, vegetables, sugar, potatoes, and other necessaries must, according to French law, be plainly posted up in view of the buyer. In this way confusion between different grades of the same article may be avoided. Extra charges for packing goods must also be plainly shown. Small merchants failing to observe the regulations mentioned are being continually fined. It would almost appear that the delinquents find it more profitable to pay the fines than to discontinue the bad practices. The vicious circles so produced are nearly always attributable to carelessness and indifference on the part of wealthy foreigners, who thus throw continually increasing hardships upon the citizens. A collateral aspect of the question is constituted by the high wages paid by foreigners to servants, who demand more than the Parisian is able to pay.

Whooping-cough.

Often in towns, and always in villages, the child suffering from whooping-cough is not isolated at home, and no precautions are taken to guard against the complications which may develop in the little patient, or to protect the other children of the family from infection. Whooping-cough is treated with contempt, because it is popularly believed to be a trivial complaint which must take its course and cannot attack adults. Further, it is the custom to send children with whooping-cough off to some friend in the country for a change of air. That is the popular estimation of the gravity of the disease, but Mr. F. Barbary, of Nice, has recently advocated that the Academy of Medicine should officially institute new and rigorous prophylactic measures. The first step would be the compulsory notification of whooping-cough, such notification at present being voluntary. The second step would be to forbid infected children to travel or mix with other children until permission was given by the doctor. The need for such measures might be brought home to the public by notices showing how whooping-cough, contrary to popular belief, can bring serious consequences, both immediate and remote, in its train. Mr. Barbary further considers vaccinotherapy to be a valuable curative and prophylactic agent in this disease.

Paris Milk.

The French Milk League, interested in improving the Paris milk-supply, has just passed a series of resolutions designed to improve the handling of milk all along the way from producer to consumer. The League especially insists on the need of clean milk for infants and young children, and on the desirability of stricter supervision of the entire dairy industry. Certain definite proposals will be presented to the municipal council by the deputy representing the quarter in which lies the Saint Louis Hospital.

Treatment of Cancer of the Rectum.

In a valuable paper on the treatment of cancer of the rectum, delivered at the recent surgical congress, Mr. Schwartz and Mr. Gaudier described the immediate and remote results of the following methods of surgical interference: (1) Abdomino-perineal excision of rectum with permanent abdominal artificial anus; (2) resection, bringing down the upper part of the rectum to form a perineal anus; (3) abdomino-perineal resection, bringing down the upper part of the rectum and preserving the anal sphincters; (4) resection by the abdominal route alone, forming artificial abdominal anus with upper part of rectum, and leaving lower part in situ after closure. The writers have further studied the respective values of surgery and radiation in the light of most recent work. Radiation treatment of cancer of the rectum has indeed made great progress during the last five years, but the results have not been so satisfactory as those obtained in treatment of cancer of the uterine cervix. Where surgery can be employed it is more valuable than radiation, and for the present, these writers hold, every case of cancer which is clearly operable should be left to the surgeon. In cases of inoperable cancer, the best results so far have been achieved by combining surgical intervention with radiation. When this combination is possible—that is, in the absence of metastases, and in patients who are neither cachectic nor too advanced in years—the method adopted should be (1) to make an iliac anus, (2) subject the patient to slow and extensive radiation, and (3) remove the cancerous growth whenever conditions permit.

The Virus of Opilaçao.

Opilaçao is a parasitic disease widely distributed among the poorer classes in Brazil, conveyed to man through the bite of a nocturnally blood-sucking hemipterous insect, the triatoma, or *barbier*. The insect occurs on the walls of dwellings. Prof. Carlos Chagas, director of the Brazilian Public Health Service, to whom we owe most of our knowledge of the disease, delivered on Oct. 23rd, at the Paris Pasteur Institute, an interesting lecture upon it, accompanied by projections. The pathogenic agent which lives in the intestine of the insect host and is highly virulent has been shown at the Cruz Institute to be a flagellate trypanosome, and it has been named *Trypanosoma cruzi*. It may infect dogs, rabbits, other laboratory animals, man, and the armadillo, the latter, indeed, serving as a reservoir of the virus. The symptoms which depend upon the organs invaded include fever, thyroid enlargement, degeneration of muscular fibres, cerebral reactions, and other effects. In dogs the signs are mainly paralytic. Like the treponema, the trypanosome may be transmitted from mother to embryo.

Congress on Stomatology.

This congress, which met from Oct. 19th to 24th, devoted much of its time to pyorrhœa. Dental bridges, vaccination, radiography, the ultra-violet rays, masseteric anæsthesia, anæsthesia of the inferior maxillary nerve trunk, and prosthesis were other subjects of interest discussed.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Resignation of Prof. F. Chvostek.

Dr. Franz Chvostek, the head of the Third Medical Clinic of Vienna, and professor of internal medicine, has tendered his resignation to the Ministry of Education, an action which has caused surprise and dismay to his numerous friends and patients. It is the more surprising as Dr. Chvostek previously resigned this office several years ago, but at the earnest request of the Ministry he withdrew his resignation and continued his work under more favourable personal conditions. Once again all efforts are being made to induce him to remain in office, and the Senate of the University has added its plea to that of the Educational Board. The third clinic, of which Prof. Chvostek was the chief organiser, has been a source of most useful scientific research ever since the work was started some 20 years ago. It may be added that the third clinic, which is still situated in the old General Hospital of Vienna, is very much handicapped by the limited space available for it in the ancient building.

Changes in the University Teaching Staff.

The well-known orthopædic surgeon Prof. Adolf Lorenz definitely resigned his professorship last spring, and Prof. Hans Spitzy has been appointed to the directorship of the University Orthopedic Ambulatorium, as it is officially termed. As successor of Lorenz, Prof. Spitzy is at present at the head of the famous orthopædic hospital in the fifth district of Vienna—the biggest of its kind in Central Europe—where he has built up a model institution for the cure, after-care, and re-education of war-crippled soldiers, that compares favourably with any other such institution in the world. The tradition of the Lorenz clinic—which is well known to American doctors—will be continued by Docent Dr. Julius Hass, the first assistant of Lorenz. He has been appointed director to an orthopædic ward and will take over this office shortly.

Closure of the Third Obstetric Clinic.

It is understood that the third obstetric clinic (Prof. Ludwig Piskacek) will be closed shortly, and with it the oldest teaching institute for midwifery in Austria, an event which means a marked diminution of the teaching facilities of Vienna. The third clinic was never intended for instruction of students, but many doctors obtained there very good post-graduate instruction, and had a chance of serving a term or two as house surgeons in the institute, thus obtaining excellent opportunities for obstetric practice. In future midwifery will be taught in the remaining two gynæcological clinics, where also the regular clinical lectures and courses for students are given.

Meteorological Conditions and Human Health.

In a lecture delivered before the Medical Society Prof. Julius Bartel discussed the influence of climatic—or rather meteorological—conditions upon the mortality statistics, giving extensive statistics and figures. Prof. Bartel's conclusions are worth consideration. He emphasises the inadequacy of our present knowledge of the climatic factors, which is obtained from post-mortem examination only, but even this is sufficient to prove that these factors have a very considerable influence on the daily mortality curve. Consideration of the constitution of the individual also shows us that the incidence of death is due not only to nature of the illness, its ætiology, and the constitution of the patient, but also to a fourth factor—namely, atmospheric conditions, such as barometric pressure, temperature, humidity, and winds. Analysis of individual cases, and control by autopsy, enable us to discern certain rules, but further research from the point of view of the clinician is very much needed. At present we can say that arteriosclerosis and tuberculosis respond to climatic changes, and the status lymphaticus usually reacts to barometric variations. It is also well known that suicides are much more frequent between April and July than in the autumn or winter. Perhaps mental conditions react differently at various periods of the year and under different weather conditions. Greater difficulty is encountered in considering the effect of climatic variations upon the "healthy" or the "apparently healthy" organism. Health and disease are only stages, very nearly related, and the susceptibility to weather factors makes itself manifest not only in the individual, but also in the masses, in the political, and social reactions of mankind.

Modern Treatment of Lupus.

At a recent meeting of the Vienna Medical Collegium Prof. Richard Volk read a paper on the treatment of lupus. He commenced with a survey of the older methods used before the advent of electrotherapy. The surgical excision of the diseased parts, immediately followed by grafting (Lang's method) was, he said, fit only for a small percentage of cases. Scraping, cauterisation, thermocautery were no longer advocated, though galvanocautery might still be applied with good results in lupus of the mucous membranes. High-frequency currents might be used for solitary nodules in the skin. The exhibition of the various tuberculins, emulsions of bacilli, had not given the satisfaction it promised at first. Chemotherapy (copper, krysolgan, salvarsan) given alone had also failed; only erythematode lupus seemed to respond favourably to krysolgan. Pyrogallol and resorcin were merely adjuvants in phototherapy as now employed for the hypertrophic and ulcerous forms of lupus. X ray treatment gave very good results, and the application might be repeated several times, a medium dosage being given. When the hypertrophic form had been transformed into a "plane" or "flat" stage, Finsen light or mercury-vapour lamps are used. Finsen laid great stress on the use of the pressure lens. Prof. Volk, however, preferred to work without the pressure lens and got better results. This method is also much more rapid and economic. General irradiation of the whole body by artificial or natural sunlight was a most useful help; of course, it was necessary to attack any coexisting tuberculous affection, such as glandular, mucous, or osseous manifestations of the disease, as well as pulmonary tuberculosis. Constant supervision and control of the patients for many years was of paramount importance to avoid relapses. The application of radium or of Ponndorf's vaccines was also useful, especially in localisations on the mucous membranes, but only in selected cases, and one must be on the look-out for possible untoward results, such as telangiectasis or hyperkeratosis.

Reorganisation of the Dental Classes of the Medical Faculty.

The new University term opened recently, and a serious shortcoming in our medical instruction has been removed by the new regulations pertaining to dental teaching of doctors. Having obtained the degree of M.D., the applicant desiring to practise dentistry will have to spend four semesters (half-years) at the institute of dentistry of Vienna. The curriculum comprises theoretical and practical instruction, and consists of classes on conservative, surgical, and prosthetic dentistry, including orthodontic and technical work in the practical laboratory. After the four semesters every student has to pass oral, written, and practical examinations. Hitherto our dental surgeons went, as a rule, to Germany to get their up-to-date experience in dentistry.

MEDICINE AND THE LAW.

Limitations of Actions against Public Officers.

Parliament has wisely recognised the fact that public servants cannot discharge their duties satisfactorily unless reasonably relieved from personal liability. In England and Wales the Public Health Act of 1875 protects local authorities, their members, and officers in this respect. The Public Authorities Protection Act of 1893 usefully enacts that no action is to be commenced against anyone for anything done in pursuance of an Act of Parliament or in intended execution of a public duty unless the proceedings are commenced within six months. The Public Health (Scotland) Act of 1897 goes further. It fixes a time limit of two months as the period after which no proceedings shall be begun against persons performing duties under the Act. The value of this protection is illustrated by a recent Edinburgh case (Gorrie *v.* Smith), where a doctor was sued in the Court of Session in connexion with the death of a patient treated at a venereal diseases centre in Glasgow. The claim arose in the following way. The claimant's wife, nursing a baby 3 weeks old, found the child apparently suffering from cold in the eyes. Dr. Elizabeth Chalmers Smith, in charge of the local child welfare clinic, prescribed an ointment and at the same time advised the mother to visit the dispensary at Black-street, Glasgow, which is an approved centre for the treatment of venereal disease. Dr. Smith had provisionally diagnosed the case as one of syphilis and she naturally wished the mother's blood to be tested. She did not inform the patient of her opinion, but gave her a sealed letter addressed to Dr. Elizabeth Helen Smith, the doctor in medical charge at Black-street. On August 6th last year the mother attended at Black-street with her baby. The provisional diagnosis was confirmed. The mother was questioned and examined, and, as a result, she was informed that her child was suffering from "poison in its blood." It was suggested that an injection should be administered which would benefit the child; it was added that an injection would act as a tonic to the mother herself. The doctor also proposed to take a sample of the mother's blood for test purposes. The mother assented to the treatment and a first injection was administered. A week later she again attended at Black-street with her child and received a second injection. She was informed that the test showed nothing. Soon after she returned home she became ill; she was removed to the infirmary and died a few days later on August 17th.

Lord Murray dismissed the action with costs. His decision was based upon the primary point that death had occurred in August and legal proceedings had not been begun until the following January, many weeks after the two months statutory time limit under the Public Health (Scotland) Act had expired. On behalf of the husband, who claimed £2000 reparation against Dr. Elizabeth Helen Smith for the loss of his wife, an interesting argument had been put forward in the endeavour to circumvent the statutory limitation which otherwise manifestly barred his claim. First, it was contended, the dead woman had not herself been a patient at all. Secondly, as she was never made aware of the diagnosis, she could not be regarded as a voluntary patient for the purpose of venereal disease treatment under the Public Health Act, so as to bring the doctor within the protection which that Act confers. Lord Murray could not accept this view. It was clear, he said, both on the admitted facts and on the documents that mother and child were alike patients. It was a case of derivative treatment and the position of the mother and the child could not be severed. He refused to hold that one and the same proceeding on the part of a medical practitioner, when plainly intended as a performance of a statutory duty, could be within or without the protection of the Act according to the precise state of knowledge of the patient as to the particular character of the disease diagnosed.

The sympathy naturally felt towards the husband in this particular case need not obscure the conclusion that such measure of protection as the Scottish Public Health Act affords was never more essential to the medical practitioner than in relation to the difficult and delicate duties performed at centres for the treatment of venereal disease. In some respects it is unsatisfactory that the medical facts of the case were not fully examined in court owing to the claim being dismissed on the preliminary ground of the statutory protection. For the claimant it was stated that both he and his first child had always been healthy and free from disease and that blood tests of himself and his two children, taken since the wife's death, had all shown negative results. The learned judge was careful to point out that there was no evidence before him as to the precise cause of death. He expressly refrained from giving any opinion or making any finding on this head. The facts were not before him. It is only fair to Dr. Smith to point out that the case ending as it did upon the preliminary objection in law, not only was there no finding that she was in any way at fault, but no opportunity arose for her to make any answer to the allegations upon which this unsuccessful claim was founded.

ST. THOMAS'S HOSPITAL WAR MEMORIAL.

The Duke of York on Nov. 2nd laid the foundation-stone of the College House Extension and Students' Memorial which is being built in connexion with St. Thomas's Hospital and Medical School. The building will be on the opposite side of Lambeth Palace-road to the hospital and will contain club rooms for students and 72 bedrooms; 12 of these will be reserved for members of the resident staff of the hospital, and the remainder will be let to junior students and others. The cost of the scheme, including the purchase of the site, will be £58,000, towards which the Medical School is raising a fund of £10,000. Sir Arthur Stanley, in welcoming the Duke of York, traced the interest in the hospital which had been taken by the Royal House from the days when Edward VI. restored it to the rights and privileges, and some of the property, which his father had taken away. Queen Victoria had laid the foundation-stone of the new buildings in 1868. Sir George Makins said that in the war 1481 of those connected with the hospital had joined up, including 214 members of the nursing staff, and of the whole number 81 had died. It was felt that no form of monument would bring the memory of those who gave their lives more constantly before the future members of the school than the provision of quarters which would be their home whilst they were working in school and hospital. The provision of this hostel was also an indication of the gradual conversion of the University of London, of which the school was a constituent college, from a purely teaching and examining body to a complete university with residential accommodation for its students. The Duke of York laid the foundation-stone with the same level as was used by Queen Victoria. The religious part of the ceremony was conducted by the Bishop of Southwark and the Hospitaller, and a guard of honour was furnished by the medical unit of the University of London O.T.C.

The late Mr. Herbert H. Folker, O.B.E.—Mr. Folker, who died on Oct. 20th in his sixty-second year after a long and painful illness, was a well-known North Staffordshire surgeon. The son of a medical man, he was educated at the Newcastle High School and at Epsom College, studied medicine at Charing Cross Hospital, and qualified in 1889 with the M.R.C.S. Eng. and the L.R.C.P. Lond. Returning to Staffordshire, he commenced practice at Shelton, and later succeeded his father as certifying surgeon under the Factory Act for the Hanley district. Mr. Folker, who took a prominent part in the movement for the compulsory notification of ophthalmia neonatorum, was appointed hon. assistant ophthalmic surgeon to the North Staffordshire Infirmary in 1892, ophthalmic surgeon in 1894, and hon. consulting surgeon in 1914. On the outbreak of war he joined the R.A.M.C. and did good service in various districts of Yorkshire, Derbyshire, and Nottinghamshire. He leaves a widow and a married daughter.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are some of the health statistics of six counties for the year 1924 :—

Name of county.	Estimated mid-year population (R.-G.).	Birth-rate.	Death-rates per 1000 of the population.				Death-rates per 1000 births.		
			All causes.	Tuberculosis.	Cancer.	Resp. diseases with influenza.	Neonatal mortality.	Infant mortality.	Maternal mort. from childbirth.
Somerset	398,300	16·3	12·3	0·80	1·40	2·3	30	54	3·7
Derbyshire. ..	607,600	20·7	11·0	0·78	0·99	2·3	34	70	3·9
Lincolnshire, parts of Lindsey	259,900	19·7	11·8	0·98	1·38	2·1	29	60	3·9
Hertfordshire ..	344,200	16·0	10·6	0·77	1·45	1·9	29	51	3·3
East Sussex ..	258,600	14·0	11·8	0·87	1·74	1·9	29	48	3·3
Cumberland ..	221,010	20·3	13·0	0·89	1·23	2·5	32	72	5·2

Somerset.

Dr. W. G. Savage reports an increase in the deaths from influenza and the diseases of the respiratory system ; the 268 deaths from influenza represent an increase of 202 over those of 1923. A table of the deaths at various age-groups during the last nine years shows that the deaths over the age of 65, which in 1911 formed 45·3 per cent. of the total, accounted for 53·6 per cent. in 1924. Twenty-five cases of ophthalmia neonatorum were notified, and there were 61 cases of encephalitis lethargica with 15 deaths, as compared with 8 cases and 3 deaths in the previous year. A special report on the mental impairment of affected school-children has been made to the Board of Education. No propaganda work with regard to venereal diseases was carried out during the year, and Dr. Savage considers that it is very difficult to arouse interest in this subject treated by itself and that it is best dealt with in courses of instruction on social hygiene along with other health matters. As regards tuberculosis he reports as unsatisfactory the fact that of 550 new cases of pulmonary tuberculosis 38 per cent. were detected in the early stage of the disease, 39 per cent. in the second stage, and 22 per cent. in the third stage and practically incurable. The percentage of contacts who attended the dispensary for examination was about 20, the figure for 1923 being 26. About 32 per cent. of the contacts of pulmonary cases showed suspicious or definite signs of tuberculosis. The new sanatorium at Quantock Lodge was not available for patients till June, 1925, and some of the buildings were used to house a holiday camp for 40 girls and 40 boys suffering from general debility and malnutrition. There were 973 new houses, compared with 648 in the previous year. In spite of urgent need, however, only 31 houses were built in Bridgwater, and in agricultural areas there has been little building. Dr. Savage refers to the subletting of parlour houses, and cites the example of the council houses in Weston-super-Mare. Of 118 houses, completed in 1922, 73 are occupied by one family, 44 by two families, and one by three families. In three instances the rent and rates were 15*s.* 6*d.* per week and the sub-tenants paid 9*s.*, 7*s.*, and 10*s.*

At Weston-super-Mare, Clevedon, and Minehead there are public slaughter-houses only, but in the rest of the county there are 350 private slaughter-houses. The new meat regulations require slaughtering to be done at fixed times or after due notice. The value of these regulations, says Dr. Savage, will largely depend upon the experience and knowledge of the sanitary inspectors, only a few of whom hold a meat certificate and some of whom have had no training in meat inspection at all. To make the new regulations of practical value facilities must be available for these men to have revision courses in meat inspection. The majority of the county's 5299 registered milk producers are taking a much greater interest in clean milk production. The control in rural districts is very unequal. In some districts the officials give only perfunctory supervision, while in other districts, such as Axbridge and Langport, much attention is being given to the work, and considerable improvements in equipment and methods are being secured. During the year there have been 32 milk demonstrations at various farms, and in the milk competition of 1924–25 30 of the competitors in the fourth series of tests attained the standard of Certified Milk, 22 that of Grade A, and only 14 failed to reach Grade A. The graded milk movement does not make much headway. At the end of 1924 there was one producer of Certified Milk, one of Grade A (tuberculin tested), and two of Grade A.

More antenatal work is being done. Cards are supplied to the midwives for recording the results of visits paid before birth. Examinations of urine, &c., are made for midwives, free of cost, in the county laboratory. Further steps have been taken to distribute leaflets to expectant mothers and the facilities for granting milk to them have been extended. Tables are given showing that over 66 per cent. of the babies 3 to 4 months old are entirely breast-fed in the rural districts and about 60 per cent. in the urban districts. The percentage of 1924 births attended by trained midwives was 50·8 and by " bona-fide " midwives 3·7. The remainder were attended by medical men, with the exception of a small proportion attended by uncertified women. The trained midwives sent for medical aid in 23 per cent. of their cases, the " bona-fides " in 12 per cent.

Derbyshire.

Dr. W. M. Ash presents the report for 1924, but only took up his duties as county medical officer on June 1st, 1925. There has been an increased prevalence of small-pox of a mild type. There were 1123 notifications, with one death in the Chesterfield district. The council has still no facilities in the county for the institutional treatment of surgical tuberculosis, but preparations are being made to provide 50 beds at Bretby Hall for the treatment of early cases of bone and joint tuberculosis in children. Of 320 deaths from tuberculosis notified by the local registrars to the county medical officers of health 120 were not notified under the public health regulations before death, 51 were only notified within four weeks before death, and 44 during the second month before death. At the end of 1924 there were 127 shelters lent out to tuberculous cases ; inspection showed that 111 were being used in a satisfactory manner and the others were not being used. The tuberculosis officer, Dr. A. N. Robertson, reports a great need for a 20 to 30-bed pavilion for advanced female cases. Most of the new " cures " are tried at the sanatoriums, but hitherto with unsatisfactory results. Dr. Robertson considers that artificial pneumothorax " is most required in an advancing toxic case of recent onset, which has not responded to three months absolute rest in bed and where the disease is mainly unilateral and the lung is breaking down, causing high fever and rapid pulse." Chronic unilateral cases of long duration with shrunken chest do not urgently require such treatment, and the adhesions frequent in such cases prevent it being successfully carried out. Dr. Robertson's experience of the after-history of large numbers of such cases is that they often do quite well without this special treatment. Five new cases were started on the treatment during the year and it was continued in four old cases. " One can positively say that by its use in picked cases a dying man can be changed in a short time into a comparatively healthy, happy individual." Dr. Robertson does not approve of beds being used for the education of advanced cases, and advocates that the education process be carried out at the home. The beds are urgently needed for early cases and the high mortality among the advanced cases after discharge gives a bad impression of the curative power of the sanatorium. After an average of ten notifications of encephalitis lethargica during the last three years there was an increase in 1924 to 84 notifications with 23 deaths. Out of 32 cases among school-children 7 died, 1 left the county, 8 showed no sequelæ, 9 showed slight or severe mental changes, 1 some physical deterioration, and 6 the Parkinsonian syndrome.

Lincolnshire (parts of Lindsey).

Dr. R. Ashleigh Glegg points out defects in the tuberculosis scheme. Many advanced cases are allowed to remain at home, partly cured cases return to insanitary homes, and there is great lack of an orthopædic scheme to prevent children being crippled by tuberculosis of bones and joints. He recommends the establishment of a central hospital with a specially trained staff and X ray department, to be fed by out-patient clinics conducted in the various districts by the hospital staff.

Dr. Annie T. Brunyate makes many recommendations for the improvement of the maternity and child welfare scheme, which are all endorsed by Dr. Glegg. More maternity homes are needed. The usefulness of the antenatal clinic at Scunthorpe will be much increased by the opening of a new six-bed home there. An antenatal clinic was opened at Gainsborough in October and one will shortly be opened at Cleethorpes. The staff of health visitors needs to be increased in order to cope with the work, and the alternative is suggested of providing them with motor-bicycles instead of push bicycles. Dr. Brunyate points out that a health visitor at the end of an exhausting day of travelling by push-bicycle cannot have the same interest in the mother nor exert the same power of persuasion as at the beginning of the day. This is so evident to the nurses that several of them have managed to run motor-cycles or light cars to their own pecuniary loss, but to the great benefit of their work. Courses of post-graduate lectures for midwives were given during the winter at Lincoln, Cleethorpes, and Scunthorpe.

Hertfordshire.

Dr. H. Hyslop Thomson states that the maternity and child welfare scheme includes both official and voluntary effort. There are 13 county council centres, 13 voluntary centres, and 9 voluntary weighing centres. Maternity beds are provided at Hertford, Hitchin, Hemel Hempstead, and Watford. There is a convalescent home at St. Leonards, and there are orthopædic, massage, and dental clinics. There is much need for additional dental clinics at Hertford and Bishop Stortford. Commenting on the increased number of deaths of infants during the first weeks of life, Dr. Thomson stresses the need for antenatal work. The births in the county numbered 5496 and only 258 expectant mothers attended the council centres. In 1923 the number was 200. Special efforts have been made to search out the mental defectives in the county, through the medium of Poor-law authorities, school attendance officers, medical practitioners, and nurses. Parents sometimes withhold information owing to the fear of their children being removed to a special school or institution. This difficulty would in time be met by the provision of an institution to which parents had easy access. The absence of adequate accommodation in certified institutions, more especially for low-grade and complicated cases, is sometimes seriously felt. A certified institution is needed which would provide accommodation for three types of case of both sexes—namely, employable, unemployable, and hospital cases. Such an institution should be so constructed as to allow for future expansion and should provide facilities for the training and employment of defectives in various occupations.

East Sussex.

Dr. Alex. G. R. Foulerton reports that the scheme for coördinating the county council's health nursing work with the general nursing, by close coöperation with the East Sussex Nursing Federation, continues to work very satisfactorily. Infant visiting under the county scheme is carried out by the nurses of the District Nurses Association, and there are only eight parishes, with a total population of about 5000, which are without the services of a district nurse. Good progress has been made with the assistance of the East Sussex Voluntary Association for the Blind in providing for the more pressing needs of the necessitous blind in the county. The recently made register of the last named includes 260 persons. In addition the county education committee provide education in special schools for blind children under 16 and secondary or technical education for certain blind persons over the age of 16 who are likely to benefit thereby.

Cumberland.

Dr. F. H. Morison reports that although the infant mortality of the county has decreased to 72, it remains in five of the urban districts at over 100. Cockermouth had an infantile mortality of 131 in 1924 and 132 in 1923. Dr. A. H. Towers, in his account of the work of the clinics at Cleator Moor and Millom, comments strongly on the ill-health of some of the mothers. He says that in these districts the poorest and most ill-nourished infants are those which are being breast-fed, and the full effect of continued unemployment, poor feeding, and housing is there seen. "The average mother is quite unfit to feed an infant by the breast; it is quite a common occurrence for mothers to arrive at the clinic markedly dyspnœic and cyanosed, with tachycardia and general cardiac irregularity, and anæmia is found to be intense." Under such conditions, he says, the infant is deriving no good from breast feeding, while the damage to the mother's health is profound. On weaning the improvement in the infant is obvious, but the mother living under these conditions only recovers slowly. At Cockermouth there is no infant clinic, but there are clinics at two other districts which have infant mortalities of 100 each—namely, Egremont and Arlecdon-cum-Frizington. 186 cases of small-pox were notified in the county during 1924 with no deaths. The Englethwaite Industrial Colony for consumptives is to be closed at an early date and its conversion into an institution for delicate children is under consideration. The average number of beds occupied at the colony during the year was 33, and there has been less demand for the beds on the part of ex-Service men with pensions. The net cost of the colony during the year, after allowing for payments for ex-Service men, receipts from the market garden, poultry farm, clog making, and joinery and all other credits was about £4000.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED OCT. 24TH, 1925.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 67; scarlet fever, 2602; diphtheria, 1240; enteric fever, 65; pneumonia, 965; puerperal fever, 43; cerebro-spinal fever, 5; acute poliomyelitis, 11: acute encephalitis, 4; encephalitis lethargica, 42; dysentery, 8; ophthalmia neonatorum, 115. There were no cases of cholera, plague, or typhus notified during the week.

Deaths.—In the aggregate of great towns, including London, there were 4 deaths from enteric fever, 25 from measles, 11 from scarlet fever, 15 from whooping-cough, 38 from diphtheria, and 41 from influenza, the last named being a slight decrease from the previous week. In London itself there were 10 deaths from diphtheria, 1 from whooping-cough, 8 from influenza, and 31 deaths of infants under 2 years of age from diarrhœa and enteritis.

SCHOOL MEDICAL SERVICE.

THE following is a summary of the reports of school medical officers:—

Name of district.	No. on roll.	Av. elem. school attendance.	No. of routine children examined.	No. of special examinations and re-inspections.	Percentage of children found on routine examination requiring treatment.*
Cambridgeshire C.C. ..	9,897	8,993	2,927	5,979	11·6
Gloucestershire C.C. ..	41,022	—†	11,805	8,298	37·8
Durham C.C.	—†	125,183	39,235	18,113	24·8
Northumberland C.C. ..	—†	—†	14,937	11,725	20·09
Lindsey C.C.	39,018	—†	11,651	6,651	15·95

* Excluding dental defects and uncleanliness. † Not given.
C.C. = County Council.

Cambridgeshire.

Dr. F. Robinson gives interesting figures showing the gradual decrease in malnutrition from 19·4 per cent. in 1914 to 4·1 in 1920, and the rise again to 11·8 per cent. in 1924. The nutritional standard of the school-children apparently varied directly with the wages and state of employment. Cod-liver oil is supplied to all ill-nourished children, but only a few of the worst cases of malnutrition are sent to the residential open-air schools run by neighbouring authorities. The standard of cleanliness is apparently satisfactory, though no cleansing surveys are carried out by the district nurses who act as school nurses. The teeth of all children from 5 to 14 years were inspected and only 36·2 per cent. were found to require treatment, and of these 65·1 per cent. actually received it. The necessity for adopting some scheme for orthopædic treatment is stressed, as is also the need for appointing a physical training instructor. No special classes or schools are run for abnormal children, but it is hoped to start some classes for backward children in the near future. Strong comment is made on the unhygienic state of many of the non-provided schools.

Gloucestershire.

In addition to "cleansing surveys," much home treatment is given in the outlying districts by the district nurses who carry out the school duties, and Dr. J. Middleton Martin points out there has been a 60 per cent. reduction of pediculous heads since the inception of the school service in 1908. In the same time defects of the nose and throat have been reduced by 30 per cent., largely owing to the increased attention given in early life. A beginning has been made in the orthopædic treatment of physically defective children. One of the surgeons from the Cheltenham General Hospital visits neighbouring schools and it is hoped that further provision will shortly be made. A few schools make their own arrangements for feeding necessitous children but no official provision is made, and Dr. Martin rightly deplores the absence of any open-air schools in the county. 60 per cent. of the children examined (6 to 9 years inclusive) required dental attention and of these 70 per cent. obtained treatment. No special provision is made for physically or mentally defective children.

Durham.

Dr. Sydney Havelock, the deputy school medical officer, in the absence of the school medical officer, Dr. T. Eustace Hill, presents a well-written and interesting report. He rightly states that one dental officer can only touch the fringe of the dental work in a county like Durham, and urges the necessity for open-air school provision and for the adoption of an efficient orthopædic scheme, &c. Arrangements are now being made for a definitely organised scheme for operative nose and throat treatment. Interesting features are the short extracts of reports from the assistant school medical officers on the actual conditions found at the examinations; these are essentially of more value than the mere recording of statistical data. Dr. Lance Stanton-Cook calls for the earliest possible treatment of squint, and makes a strong plea for the employment of an oculist in the child welfare scheme. Dr. H. G. Donald definitely associates the prevalence of threadworms with defective personal and general hygiene. To see toddler children and pet dogs engaged in a necessary part of their toilet in the street, where later will be the mud-pies, is to solve the mystery of the method of conveyance of the eggs of the oxyuris. Dr. Lillie Johnson finds that healthy girls who take regular exercise suffer no disability during the menstrual periods. Institutional care is found for most of the blind, deaf, and epileptic children, while the council provides a residential school for mentally defective children.

Northumberland.

Apart from a few remarks on nutrition, Dr. W. F. J. Whitley confines his report mainly to the statistical returns required by the Board of Education. It is thought that since only one whole-time and one part-time dentist are employed, the medical inspectors could keep the dentists fully employed in treatment and do away with the necessity for dental inspections. The assistant school medical officers referred for treatment 2293 children with four or more carious teeth, but only 1414 children received treatment, apart from 600 re-treated during the year. The value of the statistical dental return must be negligible in comparison to the waste of the dentist's time. The numbers of exceptional children in the county appear very small; for instance, there are only 138 feeble-minded and 114 crippled children. No special provision is made by the council for such children. Dr. O'Connell O'Sullivan concludes that the malnutrition existing in the children is due to defect in the quality rather than the quantity of food; and Dr. W. L. M. Gabriel has drawn up an interesting table showing the relation of weight to height at various ages, and compares the results with similar data from Newcastle, from the Anthropometric Report of 1883, and from Detroit, U.S.A.

Parts of Lindsey (Lincoln).

Dr. Ashleigh Glegg stresses the value of coördination between the various branches of the public health activities. It is an advantage for medical officers and nurses to meet parents in more than one capacity, but we do not like the idea of associating the nurses with the work of the attendance officers. Commenting on the dirt and dust brought into the schools, Dr. Glegg suggests the children should change into slippers at school. This is an ideal not easily attained. Favourable comment is made on a dust-allaying preparation, to which a trial has been given. Interesting account is given of the working of the open-air schools, and "the newest schools now in course of construction . . . can, if desired, be thrown open entirely to the fresh air." There are no institutions for the blind, deaf, mentally or physically defective children in the area, but for the great majority of the blind and deaf outside accommodation has been found. The difficulty of providing special schools in rural areas is recognised, but a step in the right direction would be the establishment of special classes at the bigger centres. The adoption of an orthopædic scheme is now being considered. An inquiry into the alleged decadence of the rural child showed that in Lindsey the country child compares favourably with the town child.

ROYAL SOCIETY OF ARTS.—A conference will be held at John-street, Adelphi, W.C., on Monday, Nov. 9th, from 5 to 7 P.M., Sir Francis Champneys in the chair, when the subject for discussion will be How the Midwife can Help in the Reduction of Maternal and Infantile Mortality. The principal speakers include Dr. John S. Fairbairn, Miss E. M. Doubleday, Lieut.-Colonel Fremantle, and Sir John Robertson.

Correspondence.

"Audi alteram partem."

UNIVERSITY COLLEGE, LONDON: A CENTENARY APPEAL.

To the Editor of THE LANCET.

SIR,—May we ask the hospitality of your columns for an appeal issued under the patronage of H.R.H. Prince Arthur of Connaught, and the vice-patronage of the Chancellor of the University of London, the Earl of Rosebery, for £500,000 to enable University College, London, upon the completion of the first hundred years of its work, to start unhampered upon its second century?

The foundation-stone of University College was laid in 1827, after two years of preparatory work following upon the famous letter of Thomas Campbell to the *Times* of Feb. 9th, 1825, in which the foundation of a University of London was first proposed. The object of the new University was to give education without regard to class or creed, and more particularly in a large number of new subjects, which did not at that period form part of the ordinary University curriculum. In the words of an early report: "It was for a class of sciences, the knowledge of which is not profitable to the possessor in a pecuniary point of view, but which exact a great influence on the well-being of society, that such an institution was required."

If this work is to continue, on the scale which the present century demands, a sum of at least £500,000 is urgently necessary. Of this total £225,000 is needed for the endowment of teaching; other urgent needs are the provision of a great hall, the reconstruction and endowment of the libraries, and the completion of the engineering equipment. The laboratory teaching of engineering is one of many subjects in which University College has done pioneer work.

University College was the first of that group of new universities which have now spread, not only through England, but to all parts of the Empire. But, owing to its position as the oldest and largest College of the University of London it must always possess peculiarly heavy obligations and responsibilities. We appeal with confidence to all citizens of London and of the Empire to help it to discharge those obligations in a manner worthy of the Empire in the capital of which it is stationed.

Donations, large or small, can be sent to Sir Robert Kindersley, G.B.E., hon. treasurer of the Centenary Appeal Fund, at University College, London, from whom the complete appeal document can be obtained.

We are, Sir, yours faithfully,

CHELMSFORD,
Chairman, University College, London.
E. A. GARDNER,
Vice-Chancellor, University of London.
MESTON,
Chairman, Appeal Committee.
R. M. KINDERSLEY,
Treasurer, Appeal Committee.
W. SETON,
Hon. Secretary, Appeal Committee.

Gower-street, London, W.C. 1, Oct. 28th, 1925.

X RAYING OF TEETH.

To the Editor of THE LANCET.

SIR,—When a physician of reputation and position writes in criticism of any method of investigation, such a communication naturally commands respect. Sir Gould May criticises the common and routine examination of the teeth by means of X rays, and draws, in my opinion, certain unfair adverse conclusions.

Now if, as he says or implies, it is so easy a matter for a dental surgeon to give a definite opinion on the condition of the teeth, or that part of the tooth which is invisible, why are so increasingly large numbers of dental surgeons going to the expense and trouble of equipping themselves with X ray apparatus? I had been of the opinion that X ray examination was advisable in certain broad classes of case. First, cases referred by the dental surgeon himself, in order to demonstrate with precision the exact condition of a root and its socket; secondly, cases referred by a surgeon, preliminary to any operation of magnitude, in order to eliminate any possible latent source of infection.

In a very large number of such cases, contrary to Sir Gould May's suggestion, the radiologist is able to report favourably. I had looked upon the above as evidence of extreme care on the part of the surgeon, and Sir Gould May's criticism, if correct, is disconcerting. Nevertheless, for my part, I should prefer to be operated upon by a surgeon who errs on the side of extreme caution.

I am, Sir, yours faithfully,

STANLEY MELVILLE.

Chandos-street, Cavendish-square, W., Nov. 2nd, 1925.

To the Editor of THE LANCET.

SIR,—The question raised by Sir Gould May in your last issue is one that, as indeed his letter indicates, concerns not only the general physician and surgeon, but also the specialists in almost every branch of medicine and surgery. An unbiased observer of our profession and its ever-changing doctrines will note that, whenever a new "craze" arises there are always those who support it and those who condemn it as new-fangled nonsense. The former are often to blame for lack of judgment and critical powers, the latter for not taking the trouble to understand the point at issue.

I suppose there is no subject in medicine on which more nonsense has been written and said as on what is commonly known as "the theory of focal infection"! To begin with, it has always been a mystery to me why it should be called a theory. A patient, let us say, has a mass of tuberculous glands in the neck, or a tuberculous focus in one lung; he then develops tuberculide skin lesions, or renal tuberculosis, or spinal caries. It is hardly theoretical to attribute these secondary complications to infection, via the blood stream, from the primary focus. Yet if one is dealing with a patient who is obviously suffering from a non-tuberculous chronic infection, and one tries to locate the main closed foci, from which invasion of the blood stream with toxins or bacteria may be taking place, one is condemned as a victim of "the theory of focal infection"! I cannot personally see any difference between X raying the teeth or the maxillary antra, and having the urine examined for bacilluria, or the Wassermann reaction performed. To my cost, I have in the past accepted the opinion of dental surgeons, whom I did not know, that "the teeth are all right." In one such case I wasted two years of a patient's life for this reason; she had the most extensive apical infection of the teeth with invasion of bone, and I have never seen a more dramatic change in a person's appearance than occurred after removal of the teeth and scraping away the diseased bone. Unfortunately in patients with chronic streptococcal infection it is not, as a rule, a question of locating one or more accessible septic foci, for such cases often have a diffuse infection of the nasopharyngeal and intestinal mucous membranes, to say nothing of closed foci in lymphatic glands. Unless everything possible is done *after* the removal of obvious accessible foci to raise the patient's resistance to his infection by means of an out-of-door existence, heliotherapy, autogenous vaccine treatment, and a suitable diet, disappointment is bound to result in the majority of cases, and such after-treatment is often impracticable. It is the actual infecting organism and the patient's resistance to it that are the important factors, and they are often entirely neglected even by those who admit the importance of focal sepsis. Sir Gould May's contention that continental medical men do not attribute the same importance to focal infection from the teeth as we do is, in part, true, although the most exhaustive treatises on the effects of pyorrhœa are by French authors. But if we are to be accused of being crazy on this subject, the French can with equal justification be accused of being crazy on hereditary syphilis and tuberculosis.

In conclusion, I would say that the last three reports I have received from dental radiologists stated that there was no evidence of infection of the teeth; and that, even if there is obvious dental sepsis, I do not advise extraction unless I consider the patient's condition warrants it, for artificial teeth can never be an effective substitute for the real article.

I am, Sir, yours faithfully,
H. W. BARBER.
Devonshire-place, W., Nov. 2nd, 1925.

To the Editor of THE LANCET.

SIR,—It would be interesting to know on what experience Sir Gould May bases his remark that "everyone whose apparently sound teeth are X rayed is said to have diseased ones." Simple inspection of a tooth does not reveal the presence of a root abscess, and many sufferers from maladies, undiagnosed by eminent specialists, are relieved when X rays expose a septic focus and an offending molar is removed. Sir Gould May's informant on the continental attitude to this question is in error, for in the Zentral Röntgen Institut in Vienna there is a special section devoted to the study of teeth alone, with results which well satisfy the Viennese doctor. Taking the line of argument adopted by Sir Gould May, it would be just as competent for the radiologist to urge the physician to give up percussing the chest and to relegate his stethoscope to the dustbin. The argument in his case would be even stronger, for physical signs in diseases of the lungs reveal very superficial infiltration, leaving it for the radiologist to discover the more deep-seated mischief. It is not in this way that progress in medicine is made.

I am, Sir, yours faithfully,
PETER KERLEY, M.B., Ch.B. (N.U.I.),
D.M.R & E. Camb.,
Zeugnis der Universität (Vienna).
Richmond, Surrey, Nov. 1st, 1925.

STANDARDISATION OF BACTERIAL VACCINES.

To the Editor of THE LANCET.

SIR,—I am doubtless not alone in welcoming Major Brown's method of making the standardisation of vaccines a more certain procedure as outlined in his letter in your issue of Oct. 31st. Admittedly, the ordinary opacity method such as Gordon's is a rough and ready procedure, but I am sure it does compare quite favourably with any counting method. Apart from cholera vibrios, the opacity is the thing we want, if we cannot have weight, for it is the amount of bacterial substance that matters. Counting methods can take no stock of autolysed organisms, and the standardisation of the streptococcal vaccine by counting methods seems to me to be futile, for in a well-shaken vaccine some of the chains break up into diplo-, triplo-cocci, into chains of all kinds of length, and some cocci autolyse so that one is quite at sea to know what constitutes a single streptococcus. Wherefore in this case an opacity method is probably the more correct, but it may be questioned whether any known method of standardising streptococcal vaccines is satisfactory. The same applies to staphylococcal vaccines, but perhaps not quite so forcibly.

Too much importance should not be attached to *any* vaccine count, for no two patients have the same toleration and no two vaccines have the same toxicity. That fine adjustment which makes for success in vaccine therapy is born of long experience and is a comparatively rare quality, but I am equally sure that some practitioners have an uncanny flair both for choosing the right case for vaccine therapy and for giving the optimum dosage. It will also be noted that for curative specific therapy stock vaccines are of very limited value, since in a mixed vaccine the correct dose of the requisite organism is masked by dilution with other unnecessary organisms, and their inelastic composition is rarely likely to be compatible with any given case.

We owe a great debt to Major Brown for his work in correlating weight and opacity standards.

I am, Sir, yours faithfully,
A. GEOFFREY SHERA, M.D. Cantab.
Welbeck-street, W., Nov. 1st, 1925.

Obituary.

GEORGE HAYNES FOSBROKE, M.R.C.S. ENG., D.P.H.

THE death is announced of Dr. G. H. Fosbroke, medical officer of health for Worcestershire, at Bidford-on-Avon, Warwickshire, after nearly a year's illness.

George Fosbroke was born in 1850 at Bidford-on-Avon, where his family have been known for more than 500 years. He was educated at St. Michael's College, Tenbury, and Swansea Grammar School, and entered Westminster Hospital in 1867. Having become an L.S.A. in 1871 he acted as assistant surgeon to the National Society during the Franco-Prussian War, and for his services was given the war medal by the French Government. He took his M.R.C.S. diploma in 1872, and for two years occupied the posts of resident obstetric physician and resident house physician at Westminster Hospital. In 1873 he returned to his own county as whole-time medical officer of health to the Stratford-on-Avon Combination of Sanitary Authorities, which included Poor-law unions in Worcestershire, and thus became one of a very small number of whole-time officers for groups of sanitary districts. In 1875 he sat for the first examination at Cambridge for the Diploma in Public Health, and in 1881 became President of the Birmingham and Midland Association of Medical Officers of Health. The Worcestershire County Council was one of the first to appoint a county medical officer of health; the decision to do so was not reached without considerable opposition, and meetings of protest were held in a great number of places in the county. The county council was fortunate enough to appoint Dr. Fosbroke as county medical officer in 1890 and with his assistance became one of the most progressive authorities in promoting public health measures. Dr. Fosbroke acted as adviser to the Gloucestershire County Council from 1900–02, and was the representative of the Local Government Board on the London Sanitary Inspectors' Examination Board, and examiner for the Royal Sanitary Institute. In 1902 he was largely instrumental in founding the Knightwick Sanatorium for tuberculosis which, starting with 16 beds, became in 1915 the King Edward VII. County Memorial with 86 beds. Though not a profuse writer, he contributed several articles to professional journals, and his routine reports to the county council contained matter of more than ephemeral interest.

Dr. Fosbroke's quiet and unassuming manner of overcoming difficulties and prejudices bore fruit in much valuable work for his county. His friendly relations with his colleagues in general practice in days when friction was common was shown by his election as president of the Worcestershire and Herefordshire branch of the B.M.A. in 1894. As a man few were more welcome in any sphere of life. He was a keen sportsman, and until prevented by an accident was well known to followers of three Midland packs of foxhounds as a hard rider. In 1887 he married Miss Mary Thorpe Lane, of Dorsington Manor, Gloucestershire, but he has left no children.

NINA HENRIETTA BEATH, M.B., Ch.B. Edin.

The death of Miss Nina Beath in London on Oct. 27th follows rapidly on her return from her work for the Presbyterian Church of England at the Women's Hospital, Swatow, China. She had been unwell for some months, but only gave up her arduous duties at the hospital at the beginning of June and reached London on Oct. 3rd. The daughter of the late Lieut.-Colonel John Henry Beath, C.B., R.A.M.C., she was born at Stirling in 1872, and after taking her degrees at Edinburgh in 1902 she went out to Swatow two years later. Her death deprives the English Presbyterian Missions in China of their leading woman member. In addition to her hospital duties she trained many Chinese students of medicine, employing for the purpose their own language, of which she was a master. She was also as active as her medical duties would allow her to be in the evangelistic work of the missions, and often preached to large gatherings of women and children.

Medical News.

UNIVERSITY OF LONDON: *University College Hospital.*—Four lectures on the History of Medicine, illustrated by lantern slides, will be delivered at University College Hospital Medical School by Dr. Charles Singer on Thursdays at 4.15 P.M., from Nov. 12th to Dec. 3rd. The subjects will be the History of Influenza, Diphtheria, Enteric Fever, and Small-pox, and the lectures will be open to all medical students of the University of London.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An ordinary quarterly Comitia of the College was held on Oct. 29th, the President, Sir Humphry Rolleston, occupying the chair. The following candidates having passed the necessary examinations were admitted as Members of the College:—

Drs. William F. Addey, Harold G. Anderson, Tridib Nath Bandgopadhyay, Ambuj Nath Bose, Reginald T. Brain, Oscar Brenner, Frederick J. H. Campbell, Weldon D. Champneys, Samuel H. Cookson, Gerard J. Crawford, Thomas H. Crozier, Cyril L. Elgood, Rowland B. Fawkes, Louis Forman, William I. Gerrard, Paul C. Gibson, Francis H. K. Green, Geoffrey Hadfield, Frederick W. Hamilton, Richard A. Hickling, Ronald E. Lane, Edward B. Marsh, James Maxwell, Alan A. Moncrieff, Benjamin B. Morgan, Milroy A. Paul, Wilfred P. H. Sheldon, John F. Smith, Norman W. Snell, Frederick H. W. Tozer, Francis C. O. Valentine, Richard H. Wade, George F. Walker, and Adam White.

Licences to practise physic were granted to 211 candidates (including 36 women) who had passed the necessary examinations. The following are the names and medical schools of the successful candidates:—

A. R. Adderley, St. Thomas's; R. D. Aiyar, Madras and London; V. M. Albuquerque, King's Coll.; C. R. Alderson, Univ. Coll.; R. B. Alston and R. C. Amies, St. Thomas's; Leah Appell, Charing Cross; H. K. Ashworth, Manchester; A. A. Atkins, London; D. G. Balakirsky, Liege and Middlesex; C. V. N. Baldry, Sydney and St. George's; W. A. Ball, King's Coll.; K. Bandaly, Univ. Coll.; J. V. Bannehr, St. Bart.'s; T. F. Barlow, London; J. M. Bassett, Edinburgh; J. R. Beal, Manchester; A. D. Belilios, St. Thomas's; H. S. Bell, Liverpool; W. T. E. Blackmore, Cardiff and London; Kathleen Blake, King's Coll.; V. H. Brink, Oxford and London; J. M. Brodrick, Liverpool; G. P. Brooks and W. Buckley, London; Margaret A. L. Buckner, Univ. Coll.; Olive K. Burnett, Royal Free; Isabella M. G. Butler, Univ. Coll.; J. P. Carpenter, Birmingham; Fanny L. Cattle, Univ. Coll.; R. T. Chadwick, Cambridge and St. Bart.'s; W. S. Chapman, Univ. Coll.; Dorothy A. Chown, Royal Free and St. Mary's; L. M. Clark and C. D. Cogswell, King's Coll.; R. Collins, Leeds; A. N. Coomarasamy, Madras and London; P. F. S. Court, Guy's; Anne A. Craig, Royal Free; P. E. J. Cutting, St. Bart.'s; A. J. Daly, London; A. C. Dalzell, King's Coll.; S. W. Davies, Cardiff; G. Dietrich, St. Bart.'s; J. Dockray, Cambridge and St. Bart.'s; W. H. Dowell, Guy's; Muriel E. Drew, Bristol; J. J. F. Dunn, Calcutta and St. Mary's; Dorothy Durance, Royal Free; J. Y. Eccles, St. Thomas's; N. L. Edwards, Manchester; A. Elliott, Guy's; Norah A. M. Empson, King's Coll.; Brenda H. English, Royal Free; I. A. Evans, Cardiff and Manchester; O. F. Farndon and R. R. Fells, St. Bart.'s; S. J. Firth, Manchester; P. H. Flockton, St. Bart.'s; A. C. Gairdner, Oxford and London; S. E. Gawthrop, Cambridge and Durham; H. Geary, Manchester and Guy's; J. F. E. Gillam, St. Thomas's; B. M. C. Gilsenan, St. Bart.'s; G. N. Golden, London; J. G. Goodman, Guy's; M. Gottfried, St. Mary's; E. P. Gough, Cambridge and St. Bart.'s; Phyllis M. Grainger, Birmingham; H. W. Greenwood, Middlesex; Margaret H. Greg, Royal Free and Manchester; G. J. Gregerson, Adelaide and London; J. C. P. Grey, Cambridge and St. Thomas's; H. R. Griffin, Middlesex; Sarah P. M. Griffiths, Cardiff and Westminster; T. A. Griffiths, Liverpool; W. S. Grove, Cambridge and Guy's; L. J. Haydon, Cambridge and St. George's; A. B. Hewlett, King's Coll.; J. D. Hindley-Smith, Cambridge and St. George's; J. C. Hogg, Cambridge and St. Bart.'s; D. P. Holmes, Westminster; L. Holmes, St. Bart.'s.; T. K. Homer and J. P. Huins, Birmingham; Ruth T. Hurnard Royal Free; D. S. Jackson, Madras and St. Mary's; I. A. Jackson, Cambridge and Guy's; Isabel E. S. James, King's Coll; R. Jones, Cardiff and Charing Cross; Adele A. Kahan, Charing Cross; M. E. Lampard, Cambridge and King's Coll.; I. Landon, St. Bart.'s; D. M. Lang, Guy's; C. G. Le Couilliard, Middlesex; A. H. Levers, Cardiff and Westminster; H. M. Levy, Middlesex; S. Levy-Simpson, Cambridge and London; R. Lewthwaite, Middlesex; D. W. E. Lloyd, Guy's; Mary C. Luff and Joan L. Lush, Univ. Coll.; J. D. S. McGeoch, Birmingham; B. W. S. Mackenzie, Cambridge and Univ. Coll.; W. K. McKinstry, Cambridge and St. Bart.'s; S. B. Malik, Punjab and Charing Cross; Margaret C. Malone, King's Coll.; C. Marian, Univ. Coll.; R. Marnham, Cambridge and St. George's; R. G. Mathews, Oxford and Univ. Coll.; R. C. May, Guy's; K. V. Mead, St. Thomas's; J. A. A. Mekelburg, Cape and Guy's; Clara Mendelssohn, Westminster; R. D. Milford, Cambridge and St. George's; Mary A. Monro, Royal Free; D. G. Morgan, Cardiff; Gertrude M. E. Morgan, Cambridge and St. Mary's; W. S. Morgan, Cardiff and St. Bart.'s; G. C. Morris, St. Mary's; Una F. M. Morton, Univ. Coll.; W. Murphy, Leeds; R. G. Nethery and F. M. Newnham, Guy's; H. A. Nicholls, St. Bart.'s; G. A. H. Norman, Westminster; D. W. C. Northfield, Guy's; H. E. Nourse, Cambridge and Middlesex; Eileen A. Nugent, Royal Free; T. C. Oakley, Birmingham; M. Odess, St. Mary's; D. Oliver, St. George's; C. J. S. O'Malley, St. Thomas's; A. Orliansky, Geneva and Middlesex; Sharada G. Pandit, Bombay; C. F. Parry, Cardiff and Guy's; F. B. Parsons, Cambridge and St. Bart.'s; G. Paterson, St. Thomas's; H. L. Peake, Guy's; L. V. Pearson, Cambridge and St. Bart.'s; B. Perchman, Charing Cross; J. D. L. Perera, Ceylon and London; D. Plum, St. Thomas's; C. G. E. Plumstead, Cambridge and St. Georges; F. H. Pratt, Guy's; J. D. Procter, Cambridge and Univ. Coll.; W. E. H. Quennell, St. Bart.'s; R. L. Quilliam, King's Coll.; R. J. Rankin, Cardiff and St. Bart.'s; J. D. Rear, Guy's; L. D. Richards, Charing Cross; K. E. R. Robertson, Calcutta and St. Mary's; P. H. Rossier, Lausanne and Zurich; C. J. Rozario, Calcutta and St. Thomas's; E. J. Rubra, Westminster; N. .L Russell, St. George's; I. J. Sachs, Middlesex; K. G. Salmon, Cambridge and St. Bart.'s; J. N. Sankey, Birmingham; Ethel M. Sargant, Cambridge and St. Mary's; A. G. Schroeder, Adelaide and London; C. R. Selous Jones, Cambridge and St. Thomas's; E. M. Shackel, Cambridge and St. Thomas's; J. W. Shackle, Cambridge and Guy's; Sara C. A. Sharpe, Royal Free and St. Mary's; J. Silverstone, Westminster; T. St.J. H. Silvester, Guy's; H. Simmonds, St. Bart.'s; G. Simon, Cambridge and St. Bart.'s; E. M. Smith, Univ. Coll.; K. S. Smith, Middlesex; R. E. Smith and E. Sorabjee, Guy's; J. Spencer, St. Bart.'s; A. L. Stephen and I. H. K. Stevens, Univ. Coll.; Gertrude H. C. Stinson, Royal Free; Mary Stirk, Manchester, R. G. Strouts, London; B. R. Sworn and C. C. Taffs, St. Thomas's; G. K. Taylor, Cambridge and St. George's; S. P. Taylor, Bristol; Elizabeth L. Taylor-Jones, Royal Free; G. A. J. Teasdale, Middlesex; E. J. S. Topham, Cambridge and St. Bart.'s; Mary C. Tugman, St. Mary's; A. B. W. Van Zyl, Amsterdam and Middlesex; W. A. Vickers, Liverpool; D. Vidofski, London; J. Viljoen, Cape and Manchester; R. J. Vince, Cambridge and London; D. C. Virmani, Lahore and Charing Cross; I. N. Vitenson, London; Florence M. Wallen, Cardiff; W. F. Waudby-Smith, St. Bart.'s; J. K. G. Way, Guy's; R. Wear, Durham; Elizabeth M. Weideman, St. Mary's; P. Weiner, King's Coll.; A. S. Wesson, Univ. Coll.; Joyce E. M. White, Royal Free and London; J. D. V. Wijeyaratne, Ceylon and King's Coll.; D. P. Williams, Middlesex and Cardiff; T. I. Williams, Guy's; H. L. Wilson, St. Bart.'s; H. F. Wilson, London; F. G. Winterton, Cambridge and St. Bart.'s; J. T. Woodhead, Cambridge and St. George's; A. T. Worthington, Cambridge and St. Bart.'s; and E. W. C. Woutersz, Calcutta and St. Mary's.

Dr. J. A. Nixon, of Bristol, was elected an Examiner in Medicine, to serve until July, 1927, in the place of Dr. J. W. Russell, of Birmingham, deceased.—A report was received from the President of the College who had attended the International Prison Congress as delegate.—The alterations in the by-laws relating to the examinations for the Membership were read a second time and passed. These include a provision designed to meet the case of medical men who have been engaged in special branches of practice lying outside the direct course of clinical medicine. Those over 30 will now be permitted to submit work they have published in any branch of medical science or in general literature, and if the Censors' Board decide that it is of sufficient merit they may excuse the candidate part or the whole of the examination. Another concession permits a referred candidate, in the absence of any special prohibition by the Censors' Board, to submit himself for re-examination without waiting for the expiration of six months, as has hitherto been the case. [A reference to these changes appears in our editorial columns.]—A letter from Dr. Daniel O'Connell Finigan asking that the Membership which he resigned in 1912 may be restored to him, was read a second time. The application was granted.—A report was received from the Committee of Management.—Dr. R. A. Young was re-elected a member of the Committee of Management.—The President announced the award of the Streatfeild Scholarship to Norman Leslie Capener, F.R.C.S., whose subject of research was "The Comparative Anatomy and Function of the Prostate Gland," and the award of the Jenks Scholarship for 1925 to Oliver Ive, of Guy's Hospital Medical School and formerly of Epsom College.—The award, by the University of Edinburgh, of the Murchison Scholarship for 1925 to Miss Sidney Elizabeth Croskery was also announced.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held during last month the following candidates passed in the subjects indicated:—

Surgery.—R. F. Ashkenny, London Hosp.; A. O. Dreosti, St. George's Hosp.; C. L. Froehlich, Guy's Hosp.; E. J. Newman, London Hosp.; M. Pettigrew, Sheffield; M. V. Roberts, London Hosp.; G. E. Rowan, St. Thomas's Hosp.; P. B. Skeels, Guy's Hosp.; J. Tarshish, Liverpool; M. E. G. Wilkinson, Bristol; and H. J. F. Wood, Guy's Hosp.

Medicine.—M. Bannounah, Guy's Hosp.; A. O. Dreosti, St. George's Hosp.; A. M. El Mishad, Guy's Hosp.; A. L. Evans, Cambridge and London Hosp; C. L. Froehlich, Guy's Hosp.; T. H. Harrison, Sheffield; M. Hook, Boston, U.S.A.; N. H. Ibrahim, Durham; F. G. Martin, Charing Cross Hosp.; P. B. P. Mellows, St. Bart.'s Hosp.; E. J. Newman, London Hosp.; E. H. Rampling, St. Thomas's Hosp.; F. Reynolds, Manchester; L. A. Rostant, St. Thomas's Hosp.; G. H. Shanley, Durham; and J. Tarshish, Liverpool.

Forensic Medicine.—A. F. Brighmen, Edinburgh; V. G. Crowley, Sydney and St. George's Hosp.; A. O. Dreosti, St. George's Hosp.; A. L. Evans, Cambridge and London Hosp.; W. O. H. Evans, Bristol; N. H. Ibrahim, Durham; F. G. Martin and K. G. B. McMahon, Charing Cross Hosp.; F. Reynolds, Manchester; G. H. Shanley, Durham; M. E. G. Wilkinson, Bristol; F. Winelake, Bern; and H. J. F. Wood, Guy's Hosp.

Midwifery.—J. H. Clapp, London Hosp.; T. K. Clifford, Manchester; S. W. Cuff, St. Bart.'s Hosp.; A. O. Dreosti, St. George's Hosp.; M. Hook, Boston, U.S.A.; E. P. Hyde, Manchester; E. J. Jones, Middlesex Hosp.; P. H. L. Moore, Sydney and St. George's Hosp.; T. C. Pain, Guy's Hosp.; F. Reynolds and J. B. Scarr, Manchester; and H. J. F. Wood, Guy's Hosp.

The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery: J. H. Clapp, S. W. Cuff, A. O. Dreosti, A. L. Evans, T. H. Harrison, E. P. Hyde, N. H. Ibrahim, E. J. Newman, F. Reynolds, M. V. Roberts, G. H. Shanley, P. B. Skeels, M. E. G. Wilkinson, F. Winelake, and H. J. F. Wood.

HUNTERIAN SOCIETY.—A meeting will be held at the Cutlers' Hall, Warwick-lane, London, E.C., on Nov. 9th, at 8.45 P.M., at which there will be a discussion on the Relation of Spiritual Healing to Modern Medicine. Amongst those who have promised to take part are the Bishop of Kensington, Rev. Canon Douglas, Rev. Mr. Anson, Dr. F. G. Crookshank, Dr. Edwin Ash, and Dr. M. P. Leahy. Fellows are reminded that they may bring non-medical guests to this meeting.

ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.—The forty-third meeting of the Commission was held at the Home Office, Whitehall, on Oct. 29th, Sir Arthur Worley, and later Lord Lawrence of Kingsgate in the chair. Evidence was given by Mr. A. B. Maclachlan and Mr. H. W. S. Francis, assistant secretaries, Ministry of Health, as to the public provision of health services outside the insurance scheme and the relations of these to the medical benefit arrangements. Thereafter further evidence on the general provisions of the insurance scheme was given by Sir Walter Kinnear, Mr. L. G. Brock, Dr. Smith Whitaker, of the Ministry of Health, and by Sir James Leishman and Mr. G. Wight, of the Scottish Board of Health. The Commission announce that Volume III. of the Minutes of Evidence (twenty-fourth to thirty-fourth days) and Part III. of the Statements of Evidence (Appendices XL. to LXXVI.) are now on sale in final form at H.M. Stationery Office, price 10*s.* and 10*s.* 6*d.* respectively, postage extra.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Dr. F. J. Poynton will lecture on Monday, Nov. 9th, at 5.30 P.M., in the Lecture Hall of the Medical Society of London, 11, Chandos-street, W. His subject will be Some Points in the Diagnosis of Tuberculosis in the Child, and all members of the medical profession will be welcome.—There is now in progress a course on Gynæcology at the Chelsea Hospital for Women, and on Venereal Diseases at the London Lock Hospital. The former will continue until Nov. 20th and the latter until the end of the month.—Dr. Porter Phillips and Dr. Thomas Beaton began a series of eight lecture-demonstrations on Psychological Medicine at the Bethlem Royal Hospital on Nov. 3rd, for which the fee is £1 1*s.*—At the Victoria Park Hospital a two weeks' course has been arranged from Nov. 9th to the 21st. Clinical instruction and lecture-demonstrations on the Various Diseases of the Chest will be given.—From Nov. 23rd to Dec. 12th the Royal Waterloo Hospital will hold a course in Medicine, Surgery, and Gynæcology.—For the convenience of the general practitioner, the London Temperance Hospital will give a late afternoon course (4.30 to 6 o'clock) in General Subjects from Nov. 23rd to Dec. 4th.—A course dealing with the Diagnosis and Treatment of Nervous Diseases will take place at the West End Hospital (73, Welbeck-street) from Nov. 23rd to Dec. 12th.—Copies of each syllabus, and also the general course programme, may be obtained from the Secretary to the Fellowship at 1, Wimpole-street, London, W. 1.

PHARMACEUTICAL SOCIETY.—A meeting will be held in the lecture theatre of the society's house on Tuesday, Nov. 10th, at 8 P.M., at which Lieut.-Colonel Sir David Prain, formerly director of Royal Botanic Gardens, Kew, will lecture on Some Useful Plants of India. Medical friends of members and student-associates will be cordially welcomed.

ST. THOMAS'S HOSPITAL MASSAGE DEPARTMENT.—A series of lecture-demonstrations are being given in this department on Tuesday afternoons at 4.30 P.M. by Dr. James Mennell. On Nov. 10th and 17th the subjects will be: Forced Movement—"Bone-setting" Manipulations—"Osteopathic" Manipulation.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—A meeting will be held at the Miller General Hospital, Greenwich, London, S.E., on Friday, Nov. 13th, at 8.45 P.M. The President, Dr. Arthur Davies, will occupy the chair, and a lecture will be given by Dr. W. Gilliatt on Eclampsia.

ABERDEEN UNIVERSITY CLUB, LONDON.—The bi-annual dinner is to be held at the Criterion Restaurant, Piccadilly, on Thursday, Nov. 19th, at 7.30 P.M., when Prof. H. M. Macdonald will take the chair. The guest of the evening will be Sir Humphry Rolleston, and Dr. W. A. Milligan, 11, Upper Brook-street, W. 1, will be glad to hear from any graduates (past or present) wishing to attend the dinner or join the club.

ROYAL DENTAL HOSPITAL OF LONDON, SCHOOL OF DENTAL SURGERY.—The annual dinner of the staff and past and present students of the hospital will be held at 6.30 for 7 P.M. on Saturday, Nov. 21st, at the Trocadero Restaurant, Piccadilly, London, Mr. W. H. Dolamore in the chair. On the afternoon of the same day the medical committee will be "At Home" from 2 to 5 o'clock to all past and present students of the hospital, when the various departments of the hospital and school will be open, and specimens and cases of interest shown by the members of the staff and lecturers. Medical practitioners are invited to be present.

ST. THOMAS'S HOSPITAL DINNER.—About 190 old students of St. Thomas's Hospital attended the annual dinner held at the Hotel Victoria on Oct. 30th. Mr. Samuel Osborn was chairman, and amongst those present were Sir Arthur Stanley (treasurer), Sir Cuthbert Wallace (Dean of the medical school and senior surgeon), Dr. C. R. Box, Lord Riddell, Lieut.-General Sir William Leishman, Air Vice-Marshal D. Munro, Sir George Makins, Sir Richard Havelock Charles, Sir Hector Mackenzie, and Sir Harold Downer. After dinner the Chairman proposed the health of the "Hospital and Medical School" in a speech full of interesting reminiscence. It was 57 years, he said, since he joined the hospital, and he believed that with the exception of General W. B. Slaughter he was the oldest old student that remained; he was certainly the first house physician in the new buildings and the last accoucheur at Surrey Gardens. Sir Arthur Stanley said that it was the duty of those who, like Mr. Osborn, had a store of information about the past to put it on record for the future. Small facts, like small articles of furniture, were only too easily lost. The life of hospital treasurers, he said, was increasingly difficult. In the old days a man coming into hospital with a bad foot was treated for a bad foot; but now he had his stomach X rayed and probably his teeth were removed. All this made for expense. Sir Arthur Stanley ended by referring to the new club and hostel which are being put up as a war memorial. Sir Cuthbert Wallace stated that there were 454 students at the school and hospital during the year; to provide for the education of these cost £30,000 a year, and but for the Government's grant of over £10,000 there would be a heavy deficit, no matter what economy was used. After speaking of those old students who had died during the year, Sir Cuthbert Wallace mentioned the distinctions that had been gained and athletic successes. The O.T.C. had won the cup given for the most efficient medical unit. Sir George Makins, speaking of the war memorial, thought it was very appropriate, and paid a tribute to the treasurer, the governors, and staff for the work which had made the memorial possible. In proposing the health of the Chairman, Sir George Makins said that Mr. Osborn had been one of the first anæsthetists to the hospital. In those days it was a much more serious thing to be an anæsthetist and the anxiety involved was enormously increased by the anxiety of the surgeon. Mr. Osborn had educated the British public up to knowing a certain amount of first-aid and to being able to help themselves, and not the British public only, since it was doubtful if any book except the Bible had been translated into as many languages as Mr. Osborn's. He had also won distinction as a medical practitioner in several wars and was a great traveller. After the Chairman had suitably replied there was an opportunity for informal conversation.

British Serbian Units Branch of the British Legion.—This branch is holding its annual dinner at Anderton's Hotel, Fleet-street, on Thursday, Dec. 10th, and all who worked for the Serbians, and their friends, are invited. The chairman will be Sir James Purves-Stewart, and tickets, price 7*s.* 6*d.* each, may be obtained from the hon. secretary, Oxford House, Junction-road, London, N. 19.

International Society of Medical Hydrology. A special meeting of this society to discuss the treatment of rheumatism in industry is to be held—jointly with the Section of Balneology and Climatology of the Royal Society of Medicine—on Friday, Nov. 27th, at 10 A.M., in the Barnes Hall, Royal Society of Medicine, 1, Wimpole-street, London, W. The President, Dr. Gustave Monod (France), will occupy the chair, and the following are expected to take part in the discussion: Sir George Newman, Dr. Van Breemen (Director of the Institute for Physical Treatment, Amsterdam), Dr. Frank Kornmann (Switzerland), Dr. Kahlmeter (consultant to the Direction des Pensions de Retraite, Stockholm), Dr. Louis Blanc (France), Dr. Schmidt (Czecho-Slovakia), Dr. R. G. Llewellyn, Dr. Otto May, Dr. Matthew Ray, Dr. Kerr Pringle, Dr. C. W. Buckley, and Dr. Fortescue Fox. Members proposing to attend are asked to reply as soon as possible to Dr. E. P. Poulton, 36, Devonshire-place, London, W. 1.

National Council for Mental Hygiene.—A meeting of the Council was held on Nov. 2nd at the House of the Royal Society of Medicine at which Sir Courtauld Thomson took the chair. Lord Birkenhead said that the object of the Council was to educate public opinion so that it should get away from the idea of incarceration and should regard institutions for mental diseases as hospitals. Sir Maurice Craig spoke of the difficulty of inducing the public to subscribe funds for the prevention of disease. "The British public," he said, "will do anything to try to cure disease, but will do nothing to prevent it." In dealing with insanity large sums were spent in housing patients who would never have got into their sad condition if early treatment had been available. A more enlightened attitude towards mental disorder was essential and the Council was trying to collect and disseminate evidence. Dr. W. A. Potts said that magistrates seemed to imagine that they could diagnose mental defect, though they would never borrow a stethoscope to try to diagnose heart trouble. He pleaded for fuller education of the medical profession on mental disease. Lord Southborough said that there were practically no facilities for early treatment so far as the vast majority of the population was concerned.

Liverpool Medical Institution.—At a meeting held on Oct. 29th, Mr. R. Craig Dun, the President, being in the chair, Mr. John T. Morrison read a short paper on the Surgery of the Lung. He outlined the difficulties met with in experimental work and the controversy between Graham and Duval as to the physics of the chest with a wide open pneumothorax. He then described his own experiences in performing partial and complete pneumectomies in rabbits, using ordinary open ether anæsthesia. When the whole lung was removed the animals always died, apparently as the result of the trauma to the pulmonary root, since death could always be prevented by section or blockage of the vagus in the neck. No case of sepsis had occurred although the lung pedicle was merely crushed and tied with 10-day catgut. The difference between the sterile bronchi in rabbits and the infected bronchi in man in disease was pointed out and some of the methods referred to by which the risk of sepsis from this source could be minimised. Mr. Morrison then described the gross and histological changes that occurred after total pneumectomy, alluding to the altered contour of the chest, the hypertrophy of the heart, and the twofold changes in the lung; in some emphysema, in others mainly an intense congestion. After a review of the outstanding achievements in pulmonary surgery Mr. Morrison appealed for more frequent recourse to exploratory thoracotomy, a simple and more effective operation than exploratory laparotomy. Such exploration would disclose cases amenable to surgical treatment and, more important still, lead to a knowledge of the pathology of the living chest, analogous to that which had revolutionised the treatment of alimentary diseases.

Sir William Collins has been appointed Vice-Lieutenant of the County of London.

The meetings of the Royal Commission on Lunacy and Mental Disorder are to be resumed on Nov. 10th, at 10.30 A.M., at 1, Whitehall-gardens, S.W.

Mr. W. H. Cruickshank has been appointed Professor of Physiology in the Prince of Wales Medical College, Patna, India.

Councillor Dr. W. James Susman has been elected as Mayor for the borough of Henley-on-Thames for the ensuing year.

Pioneers in Tropical Medicine.—Dr. Andrew Balfour's presidential address to the Royal Society of Tropical Medicine and Hygiene will appear, fully illustrated, in the next issue of the Transactions of the society.

Sheffield Medical Dinner.—The annual dinner will be held in the Royal Victoria Hotel at 7.30 P.M. on Thursday, Nov. 12th. Applications for tickets (12*s.* 6*d.*) should be made to the hon. secretary, Dr. J. Eric Stacey, 2, Durham-road, Sheffield.

Child-Study Society.—A lecture on the Development of Speech in the Normal Child will be delivered on Nov. 12th, at 6 P.M., by Mr. Macleod Yearsley, at 90, Buckingham Palace-road, London, S.W., Dr. James Kerr presiding.

The Minister of Health at Halifax.—Mr. Neville Chamberlain visited Halifax on Oct. 26th, and after inspecting several institutions devoted to women's welfare, opened a workshop for the blind at the Hostel of the Halifax Society for the Blind. The workshop, like the hostel, has been built under a £10,000 legacy from the late Mr. J. W. Horsfall. Mr. Chamberlain said that blindness was mostly due not to accident, but to causes which in a perfect state of society should not occur. Referring to smoke in Halifax, he said that he hoped to introduce a new Smoke Abatement Bill in Parliament in the coming year. It did not do to rely exclusively on the central authority for the control of smoke, and his object was to promote partnership between local and central authorities for this matter.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Monday, Nov. 9th.

WAR: at 5 P.M.
Paper:
Wing-Commander E. C. Clements, R.A.F.: Visual Problems and their Relation to Flying and Industrial Fatigue from the Service Standpoint.

Tuesday, Nov. 10th.

THERAPEUTICS AND PHARMACOLOGY: at 5 P.M.
Discussion on
The Influence of the Ovary on Parturition.
Other Speakers:
Mr. F. M. A. Marshall, Dr. Langdon Brown, Dr. Wilfred Shaw.
OBSTETRICS AND GYNÆCOLOGY:
Members of this Section are particularly invited to attend above Meeting.
PSYCHIATRY: at 8.30 P.M.
Presidential Address:
Dr. R. H. Cole: The Progress of Psychiatry.

Wednesday, Nov. 11th.

SURGERY: SUBSECTION OF PROCTOLOGY: at 5.30 P.M.
Presidential Address:
Mr. G. Grey Turner: The Relationship of Proctology to Greater Medicine.
A discussion will follow.
There will be a demonstration of pathological specimens.

Thursday, Nov. 12th.

TROPICAL DISEASES AND PARASITOLOGY: at 5.30 P.M.
Presidential Address:
Sir William T. Prout: Medical Conditions in Tropical Countries.
Paper:
Dr. Aldo Castellani: Typhoid and Paratyphoid-like Fevers caused by Organisms which Differ from *B. typhosus* and *B. paratyphosus* A, B, C.
Specimens:
Dr. Arthur Powell: Specimen of the Spirochæte of Rat-bite Fever from Bombay (*Treponema morsus muris*).
Dr. S. Roodhouse Gloyne: Specimen of *Tænia cœnurus serialis.*
MEDICINE:
Members of this Section are cordially invited.
NEUROLOGY: at 8.30 P.M.
Joint Paper:
Dr. Wilfred Harris and Dr. W. D. Newcomb: On a Case of Glioma of the Pons, with Special Reference to its Bearings on the Physiology of the Fifth Cranial Nerve.

Friday, Nov. 13th.

CLINICAL: at 5.30 P.M. (Cases at 5 P.M.)

Cases and Specimens:

Dr. J. H. Sheldon: Multiple Myelomatosis.

Dr. Bernard Myers: Amyotonia Congenita.

Dr. B. T. Parsons-Smith: Intrapericardial Aneurysm of Aorta.

Mr. J. D. Driberg: (1) Axillary Tumour; (2) Case for Diagnosis.

Dr. J. F. Halls Dally: Hyperpiesia and Demonstration of a New Mercurial Blood Pressure Instrument.

Dr. L. S. T. Burrell: Bronchiectasis and Cerebellar Abscess.

Dr. F. E. Saxby Willis: Specimen showing Primary Carcinoma of Left Bronchus.

Dr. E. Stolkind: (1) Case of Hypopituitarism. (2) Case of Polycythæmia Vera treated by X rays. (3) Description of Case of Fatal Medinal Poisoning.

OPHTHALMOLOGY }
SURGERY } at 8.30 P.M. (Cases at 8 P.M.)

Joint Discussion on

Plastic Operations on the Face in the Region of the Eye.

The following have promised to take part:—

Mr. H. S. Souttar, Mr. G. H. Pooley, Mr. Kilner, Mr. Percival Cole, Mr. Ormond, Mr. Shaw, Mr. Edmunds, Mr. M. W. B. Oliver.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

Monday, Nov. 9th.—8.30 P.M., Discussion on Obscure Pyrexia in Childhood, to be introduced by Dr. Robert Hutchison, followed by Dr. Wilfred Pearson, Prof. F. S. Langmead, and others.

HARVEIAN SOCIETY OF LONDON.

Thursday, Nov. 12th.—8.30 P.M. (at the Paddington Town Hall, Paddington Green, W.), Dr. J. D. Rolleston: The Differential Diagnosis of Scarlet Fever and Diphtheria, and the Modern Methods of Treatment and Prophylaxis, followed by a discussion.

THE BIOCHEMICAL SOCIETY.

Monday, Nov. 9th.—5 P.M. (at King's College, W.C.). *Communications:* J. A. Hewitt and H. G. Reeves: Tautomerism of Glyceric Aldehyde; J. A. Hewitt and H. G. Reeves: Constitution of Glyceric Aldehyde: C. Lovatt Evans: Lactic Acid Formation in Plain Muscle; Elizabeth S. Semmens: The Hydrolysis of Starch in the Guard Cells of the Stomata of a Monocotyledon; J. Gordon, J. W. McLeod, and B. Wheatley: The Importance for the Bacteriologist of Differentiating between the Amino-Acids which Favour and those which Inhibit Bacterial Growth; J. R. Marrack and G. D. Thacker: The Influence of Ionic Strength on the Equilibrium of Calcium-ion in Bicarbonate Solutions.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.

Tuesday, Nov. 10th.—5 P.M., Dr. A. Shadwell: Medicine in Ancient Egypt, Assyria, and Palestine. (First FitzPatrick Lecture.)

Thursday.—5 P.M., Last FitzPatrick Lecture.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

Wednesday, Nov. 11th.—5 P.M., Mr. James Sherren: Gastro-jejunostomy.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, Nov. 9th, to Saturday, Nov. 14th.—Fellowship of Medicine Lecture, Medical Society, 11, Chandos-street, W. Mon., 5.30 P.M., Dr. F. John Poynton: Some Points in the Diagnosis of Tuberculosis in the Child.—Bethlem Royal Hospital, Lambeth, S.E., Tues., 11 A.M., Dr. Porter Phillips: The Diagnosis and Symptomatology of Mental Diseases. Sat., 11 A.M., Dr. Thomas Beaton: Psycho-neuroses.—Chelsea Hospital for Women, Arthur-street, S.W. Post-graduate course in Gynæcology, lectures, and demonstrations daily. Pathology and operations.—London Lock Hospital, Dean-street. Comprehensive course. Instruction in the Out-patient Department and Lectures.—City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E. Post-graduate course in Diseases of the Heart and Lungs. Lectures, clinical demonstrations, and laboratory demonstrations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Thursday, Nov. 12th—3 P.M., Demonstration: Dr. J. Browning Alexander: Blood Pressure Investigations. 4.30 P.M., Lecture: Mr. J. Howell Evans: A Plea for Less Mutilating Operations in Carcinoma.

Daily: Clinics and Demonstrations in the Wards and various Out-patient Departments, Operations, &c.

UNIVERSITY COLLEGE, London.

Wednesday, Nov. 11th.—5.30 P.M., Prof. G. Elliot Smith and Dr. John Beattie: The Evolution of Man. (First of six Public Lectures.)

ST. JOHN'S HOSPITAL, 49, Leicester-square, W.C.

Tuesday, Nov. 10th.—5 P.M., Dr. H. MacCormac: Diseases due to Animal Parasites.

Thursday.—5 P.M., Dr. A. C. Roxburgh: Urticaria.

JAMES MACKENZIE INSTITUTE FOR CLINICAL RESEARCH, ST. ANDREWS.

Tuesday, Nov. 10th.—4 P.M., Dr. A. Hynd: The Estimation of Blood-Sugar.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL, Marylebone-road, N.W.

Thursday, Nov. 12th.—5 P.M., Mr. T. Stevens: Meddlesome Midwifery.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE: OCTOBER-NOVEMBER, 1925.

CLINICAL LECTURES AND DEMONSTRATIONS.

Monday, Nov. 9th.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Tremor and Incoördination: Dr. Risien Russell.

Tuesday, Nov. 10th.—2 P.M., Out-patient Clinic: Dr. Walshe. 3.30 P.M., Peripheral Neuritis: Dr. Grainger Stewart.

Thursday, Nov. 12th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Hemiplegia: Dr. Walshe.

Friday, Nov. 13th.—2 P.M., Out-patient Clinic: Dr. Adie. 3.30 P.M., Electro-therapy in Lesions of Peripheral Nerves: Dr. Bailey.

The fee for the Course, including Pathology Lectures, is £5 5*s*. For those who hold Perpetual Tickets the fee is £3 3*s*.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE PATHOLOGY OF THE NERVOUS SYSTEM.

Thursday, Nov. 12th.—12 noon, Subacute Inflammation: Dr. J. G. Greenfield.

COURSE OF LECTURES AND DEMONSTRATIONS ON THE ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM.

Monday, Nov. 9th.—12 noon, Reflex Action as a Whole: Dr. J. L. Birley.

Dr. H. J. Macbride is giving a COURSE of EIGHT CLINICAL DEMONSTRATIONS, chiefly on METHODS OF EXAMINATION OF THE NERVOUS SYSTEM in the Wards at 10 A.M. on Tuesdays and Fridays. The fee for this Course is £2 2*s*.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.

Any part of the Course may be taken separately. Special arrangements will be made for those unable to take the whole Course.

Fees should be paid to the Secretary of the Hospital at the Office on entering for the Course.

J. G. GREENFIELD, Dean of Medical School.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

Tuesday, Nov. 10th.—4.15 P.M., Mr. J. Morley: Shoulder Tip Pain.

Friday.—4.15 P.M., Prof. J. S. B. Stopford: The Sympathetic Nervous System.

ANCOATS HOSPITAL POST-GRADUATE LECTURES.

Thursday, Nov. 12th.—4.15 P.M., Mr. H. Platt: The Treatment of Common Fractures, with Practical Demonstrations.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

Wednesday, Nov. 11th.—4 P.M., Dr. Hastings Gilford: The Prevention of Cancer and Allied Neoplasias.

PEOPLE'S LEAGUE OF HEALTH, Fyvie Hall, Regent-street Polytechnic.

Friday, Nov. 13th.—6 P.M., Prof. Leonard Hill: Prevention of Tuberculosis.

Appointments.

POLLARD, J. M. W., M.D. Lond., has been appointed Senior Medical Officer, West African Medical Staff, Assistant Director of the Medical Service in Nigeria, in succession to Dr. B. Moiser, retired.

WALKER, E. W. AINLEY, M.D., B.Ch., D.Sc. Oxf., Lecturer in Pathology in the University of Oxford for a further period of five years.

WATT, ALEXANDER WILSON, M.B., Ch.B. Glasg., Junior Assistant Medical Officer at the Carlish Mental Hospital.

Certifying Surgeons under the Factory and Workshop Acts: MCCOULL, R., L.R.C.P., & S. Edin., L.R.F.P.S. Glasg. (Wylam District of the County of Northumberland); SYMONS, A. D., M.D., B.Ch. Bristol (Shrewsbury).

Vacancies.

For further information refer to the advertisement columns.

Bath, Royal Mineral Water Hospital.—Res. M.O. Aest rate of £130.

Belgrave Hospital for Children, Clapham-road, S.W.—Hon. Radiologist.

Birmingham City Hospitals for Infectious Diseases.—Sen. Asst. M.O. £400.

Brighton, Royal Alexandra Hospital for Sick Children.—H.S. £100.

Capetown, Somerset Hospital.—Res. Med. Supt. £800.

Cardiff, Welsh National School of Medicine.—Lecturer in Pathology and Bacteriology. £750.

Chesterfield and North Derbyshire Royal Hospital.—Res. Surg. O. £300. Fifth H.S. At rate of £100.

East Ham Education Committee County Borough.—Aural Surgeon. £3 3*s* per session.

Elizabeth Garrett Anderson Hospital, Euston-road.—H.P., Obstet. Asst., and Two H.S.'s. Each at rate of £50. Also Clin. Assts.

Glasgow, Lightburn Joint Hospital, Shettleston.—Res. Phys.-Supt. £350.
Lancaster, Borough of.—Asst. M.O.H. and Asst. Sch. M.O. £500.
Leamington Spa, Warneford General Hospital.—Res. H.P. At rate of £150.
Leyton Urban District Council.—Deputy M.O.H., &c. £600.
London Hospital, Mile End, E.—Asst. P. to Skin Dept. Also Hon. Dent. Surg.
London Lock Hospital, 91, Dean-street, W.—Clinical Assistantships.
Manchester, Barnes Convalescent Hospital, Cheadle.—Res. M.O. £250.
Norwich, City and County of.—M.O.H. £1100.
Oxford, Radcliffe Infirmary and County Hospital.—H.P., H.S., Cas. H.S. and Obstet. H.P. All at rate of £120.
Preston County Borough.—Asst. M.O. for Maternity and Child Welfare. £600.
Prince of Wales's General Hospital, Tottenham, N.—Hon. Anæsthetist.
Rhondda Urban District Council.—Asst. M.O. £600.
Royal College of Physicians, Pall Mall East.—Milroy Lecturer.
Royal Free Hospital, Gray's Inn-road, W.C.—Obstet. H.S., Gynæcological H.S. Also H.S.'s and Asst. Cas. O.
Royal Northern Hospital, Holloway, N.—H.S. At rate of £70. Case O.'s. At rate of £90.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Non. Res. Cas. O. £150. Also H.S. and H.P. Each at rate of £100.
St. Helen's County Borough.—Asst. M.O.H. £600.
Salford Education Committee.—Asst. Sch. M.O. £600.
Scottish Board of Health.—M.O. £500.
Staffordshire General Infirmary, Stafford.—H.P. At rate of £150.
Sudan Medical Service.—Three M.O.'s. £E720.

Births, Marriages, and Deaths.

BIRTHS.

Habgood.—On Oct. 24th, at Wolverton House, Old Wolverton, Bucks, the wife of Arthur Henry Habgood, D.S.O., M.B., of a daughter.

Parkinson.—On Oct. 30th, at 1, Devonshire-place, W., the wife of John Parkinson, M.D., of a daughter.

Pulvertaft.—On Oct. 25th, at "Cranleigh," Egham, the wife of R. J. V. Pulvertaft, M.B., of a daughter.

Spence.—On Oct. 23rd, the wife of Dr. D. Benham Spence, of Clarendon-road, Watford, of a son.

MARRIAGES.

Wells—Mason.—On Oct. 31st, at St. Mary's, Northleigh, Dr. Arthur Quinton Wells, to Rhona Margaret Alice, second daughter of James Francis Mason and Lady Evelyn Mason, Eynsham Hall.

DEATHS.

Beath.—On Oct. 27th, in St. Columba's Hospital, London, Nina Henrietta Beath, M.B., Ch.B. Edin., for 20 years missionary of the Presbyterian Church of England in Swatow, China.

Davidson.—On Oct. 28th, at Charmouth, Harold Davidson, M.R.C.S., L.R.C.P., of Teddington.

Fosbroke.—On Oct. 27th, at Bidford-on-Avon, Warwickshire, George Haynes Fosbroke, M.R.C.S. Eng., D.P.H. Camb., County Medical Officer for Worcestershire.

Pardington.—On Nov. 1st, at Tunbridge Wells, George Lucas Pardington, M.D., M.R.C.P. Lond., M.R.C.S. Eng.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

James Mackenzie Institute for Clinical Research, St. Andrews.—Sir Leslie Mackenzie on Oct. 27th read a paper on the Modern Outlook in Preventive Medicine. He said that the essential basis of all preventive medicine must be the work of the general practitioner, who comes in contact with the raw material. It was the ideal of the public services to give every assistance to the practitioner, and the only obstacle was the tendency of the official mind to be dehumanised and for the public services to become isolated instead of coöperative. Commenting on the remarkable expansion of the public preventive services in recent years, especially in the direction of supervision of expectant mothers and of child welfare treatment, he emphasised the part which must be played by the general practitioner in this development. Such institutions as the James Mackenzie Institute would be a liaison between the practitioner and the authorities. Practice under the Insurance Act was the principal field for this work, and the records obtained from the panel practitioners were very valuable. They were often crude or inaccurate, but taken in mass they gave a clear indication of the ailments responsible for loss of working time and therefore of the morbidity, as distinguished from the mortality, of the community.

Notes, Comments, and Abstracts.

CHILLED AND FROZEN MEAT.*

By W. J. Howarth, C.B.E., M.D., D.P.H.,

MEDICAL OFFICER OF HEALTH FOR THE CITY OF LONDON.

[Dr. Howarth began by paying a tribute to the efforts of the daily press to ensure the supply of pure food to people in all ranks of society. Multiple shops and restaurants with their central store and chemists and supervisors were able to ensure that the articles meet statutory requirements, and he claimed that they had diminished the sale of sophisticated foodstuffs. Going on to deal with the conditions under which food is imported, he mentioned the vast quantities of meat brought into the country in various forms. Safeguards had gradually been introduced to ensure the observance of certain essential requirements—namely: 1. That both home and imported products are in all respects sound and fit for human consumption. 2. That home products are prepared and manufactured in a satisfactory manner. 3. That products which at one time were considered satisfactory have not deteriorated and become unsound and unfit. 4. That the substitution of less desirable substances for those being purchased does not take place. 5. That the addition of objectionable material shall be prevented—e.g., preservatives. 6. That as far as may be possible products shall be composed of materials definitely stated. 7. That in those prepared foods in which certain unavoidable, but at the same time objectionable, contaminations may gain access in the course of manufacture, such contaminations shall be present in minimal and harmless amounts. Dr. Howarth then turned to the subject of refrigeration and substitution, and continued to the following effect:—]

Methods of Refrigeration.

Most of the imported meat arrives in the cold state. It is carried in chambers, the interior of which is chilled by cold, and this chilling may be produced in several ways. The most convenient method is that in which the cold-producing pipes are filled with brine and some portion of the pipes is submerged outside the room in a solution of cold brine. The brine enclosed in the pipes is chilled and made to circulate through the pipes, which are arranged in suitable ratios around the cold room. Goods deposited in cold store should be in a clean, satisfactory condition. Putrefaction is masked by freezing and only fresh material should be admitted, otherwise mustiness will result. Frozen goods which are removed from store for sale and thawed should not be readmitted. Definite responsibility should devolve upon someone to safeguard the public against stores being used to get rid of products which are in an unsatisfactory condition. A register should be kept of the products deposited. The chief requirements of the sanitary authority would be met by registration of stores, the compulsory keeping of a register of materials admitted and released, and free admission of the authority's officers to the different compartments and passages.

The chilling of meat does not retard objectionable changes sufficiently to ensure satisfactory carriage if the journey extends over a period longer than three or four weeks, and for this reason all Australian meat has to be frozen. Argentine meat is chilled, and as such meat on arrival has already almost reached the limits of exposure without deterioration it cannot be kept long after reaching this country; it has to be marketed, sold, and consigned reasonably quickly. To allow of chilled meat being conveyed over longer journeys several methods have been tried, but none of them can be considered to be of any help. Meat, being a putrescible material, may undergo change if there should be a serious breakdown in the refrigerating machinery, and since when it is frozen solid it cannot be examined satisfactorily for possible putrefactive changes, certain signs have to be looked for which indicate that the changes have occurred. Examination of the covers may be of some assistance. The white cloths in which the quarters are wrapped are put on when the carcasses are frozen hard and at that temperature they are dry. If a temperature below freezing-point is maintained during the voyage the cloths will remain dry, they will be non-adherent, and they will not be extensively stained with blood or serum. If, on the contrary, there has been some thawing of the carcasses it is obvious that moisture will be deposited on the surface of the meat, the cloths will adhere thereto, and on refreezing they will be frozen firmly to the carcass. If, therefore, when a large number of carcasses are examined, the cloths are clean and do not stick to the surface and do not show long lines of moisture or blood, it is permissible to assume that the meat is in fair condition. If there is any serious doubt an incision through the calico cloth over the convexity formed by the ribs in the forequarters, and over the hollow of the pelvis in the hindquarters, is advisable. If the changes have been pronounced mould growths may be found in these areas.

---

* Being an abstract of part of a Chadwick Lecture on the Control of the Food Supply delivered at the Royal Sanitary Institute on Oct. 30th, 1925.

Recognition of Imported Meat.

As regards substitution there is but little difficulty in recognising even small joints of frozen meat; it often, however, requires a highly experienced man to decide with certainty that certain smaller cuts are chilled and not home-killed. Home-killed carcasses, as a rule, are clean, bright, and tidy in appearance, and carefully dressed. The stifle-joint is often cut across to allow of the escape of synovial fluid, and the fat in the pelvis is often skewered to make it hang in the form of loops. In some districts the carcass is divided into two parts by chopping through the vertebræ for their whole length; in others the spinal column is sawn down as far as the dorsal vertebræ, the remainder being chopped through. The cold and set home-killed carcass is dry and somewhat greasy. On section it will be observed that there is not a large amount of moisture in the tissues, the meat being moist but not wet. The fat is usually yellowish-white in colour, tolerably firm to the touch, and free from suspicion of wetness. The side of a home-killed carcass is generally divided into hind and forequarters between the twelfth and thirteenth ribs, thus leaving one dorsal vertebra on the hindquarter. In imported meat the quarters have never the same well-finished appearance as in home-killed; the spinal column is always sawn down through the whole length, and three ribs are left connected with the hindquarter. These ribs are frequently cut off and sold separately under the name of "wing ribs."

The appearance of a joint of chilled meat may be very little different from that of home-killed on the one hand, or from frozen on the other, according to the care which has been displayed in chilling, in transporting, and on the maintenance of a suitable temperature. At temperatures below 32° F. the meat will assume the characters of frozen meat. The fat of chilled meat often acquires a pinkish hue due to the exuding meat juices, but it may be unchanged except for some roughening of the surface and edges. The outside of the meat is of a dull slate colour where the muscular bundles are exposed. On section the meat shows some excess of moisture which is most apparent on pressure.

Frozen meat is readily recognised by its unfinished appearance; the fat is dead white in colour after defrosting; the carcass in the frozen state is rigid, and the finish in varying degree rough and ragged, owing to the carcasses being packed one on top of another in transportation. Unless previously thawed the outside will be found to be covered with moisture which has condensed from the atmosphere, and on section the muscular tissue is uniformly light in colour and has thus a washed-out appearance. It is moister than either home-killed or chilled meat, the amount of moisture depending partly on the care displayed in thawing. The exposed surfaces of the sawn bones are white in frozen meat; in chilled meat obtained from young animals of good quality they retain the rose-tinted appearance usually seen in freshly killed animals.

THE MEDICAL HAND IN MODERN INDUSTRY.

Dr. Peter Howie delivered a presidential address on this subject at a meeting of the Aberdeen Medico-Chirurgical Society held on Oct. 29th. He pointed out that, contrary to usual belief, recognition of unhealthy conditions of work and trade is no new thing. Hippocrates and Galen drew attention to the dangers of such occupations as mining, pottery-working, lead-smelting, and textile-working; Pliny informed us that in Roman times polishers wore respirators to prevent the inhalation of red lead dust. In 1557 Georgius Agricola, in a book "De Re Metallica," showed that dust in mining operations may produce asthma and even lead to conditions we now recognise as consumption. In 1700 Ramazzini, of Padua, published a book, "De Morbis Artificum Diatriba," dealing with diseases produced by labour and by certain occupations and professions. The removal of unhealthy conditions of trade is, however, another matter, and may more truly be claimed as a modern development. No preventive measures began to arise till the latter part of the eighteenth century, and no very satisfactory results followed till well into the nineteenth.

After describing the horrible conditions of child labour prevalent at the end of the eighteenth century, Dr. Howie referred to the Board of Health of Manchester formed after an inquiry led by Dr. Perceval in 1784, which may be regarded as the root from which all subsequent legislation dealing with the health side of industrial activity has sprung. In 1802 Sir Robert Peel introduced a Bill, which subsequently became law, entitled "Health and Morals of Apprentices Act." During the next 40 years much legislation followed, almost always in the teeth of strong opposition. In 1819 the age of children employed was limited to 9 years, with a 12-hour day for all under 16. In 1825 work on Saturday was limited to 9 hours. In 1832 the first work on the subject by a British medical writer, Dr. Turner Thackrah, of Leeds, was published on "Diseases of Workmen." In 1833 a Royal Commission was appointed to consider the subject, and soon afterwards an Act was passed whereby, among other things, State-paid factory inspectors were first appointed; certificates had to be granted by physicians and surgeons who had to declare the individual "to be of the ordinary strength and appearance of a child of 9 years." Here we had the origin of the certifying factory surgeons, though these were first officially appointed in 1844. During the latter half of the nineteenth century legislation was prolific, and more and more attention was paid to trades and occupations involving dangerous conditions. A Shop Hours Act in 1886 first brought that class of work under control. In a Factory Act of 1891 a specially important point emerged for the first time in that the employment of any woman within four weeks after childbirth was prohibited in any factory. In 1901 another important Act made it compulsory for every practitioner to notify not only the medical officer of health of the local authority but also the Home Secretary of the occurrence of any case of anthrax, and lead, phosphorus, mercurial or arsenical poisoning of industrial origin. The various Acts dealing with Workmen's Compensation are also of great importance, especially those of 1906 and 1918.

After this historical survey, Dr. Howie went on to consider under three main heads the results achieved and the main lines along which medical science is influencing working conditions and guiding legislative efforts. Considering first industrial activity in relation to the general health of the worker, he pointed out that this is essentially the question of industrial fatigue. The problem is being studied and attacked in many ways, and it is now realised that output can best be attained by health. Many tests are being applied in the endeavour to measure the degree and incidence of this industrial fatigue, and interesting results are being brought to light through this new industrial physiology. For example, observation is proving that rhythm is of the utmost value in work, both in preventing and delaying fatigue and in increasing output; rhythm relieves monotony and aids production. Scientific study of occupational movements is proving of the utmost value by showing where unnecessary movements may be eliminated and output therefore greatly increased. Workers and their machines, benches, or seats are being adapted to each other with excellent results. In many works regular rest periods are introduced, thus lessening monotony and bringing into play a degree of rhythm which seems to be useful in the prevention or delay of fatigue. Other factors are ventilation, temperature, humidity of atmosphere, and lighting, and these are all being studied and the results applied for the benefit of the worker.

After indicating briefly the importance of the different types of industrial disease coming under the cognisance of the Home Office, and those entitling to compensation, Dr. Howie considered the chief methods by which medical knowledge influences industrial conditions. He referred to official control by means of Parliamentary legislation and regulation by the Home Office, carried out through the instrumentality of the factory and mines inspectorate composed of men and women of high technical skill, with a medical inspectorate which is constantly studying conditions of labour and new aspects of disease conditions which might seem to be due to labour or the circumstances under which it is carried out, with the aid of many of the physiological and other laboratories in the country where industrial problems are sent to be solved. In addition, there is a numerous body of certifying surgeons throughout the country, undertaking the routine examinations, often assisting in special investigations, and possessing many powers for safeguarding young workers. There is, finally, the industrial welfare movement, which, beginning in small ways before the war, attained great importance during the war and reached such important dimensions that the Factory Acts now take cognisance of welfare work, and in many cases lay down certain minimum requirements. In large institutions this work is under specially trained and appointed supervisors, for whose training and qualifications the Home Office lays down certain regulations. After describing their duties, Dr. Howie referred to the Industrial Health Education Council, a body whose purpose is to "educate industrial workers on the diseases and sicknesses to which they are liable, with the view to investigating and preventing the same." This body, he said, will prove to be of much service in cases where it is not possible to have welfare schemes and supervisors. The method of work is by means of lectures to bodies of workers themselves, organised by their unions and similar organisations.

I-EM-HETEP.

To the Editor of The Lancet.

Sir,—The interesting annotation concerning this deity in your issue of Oct. 17th will give much pleasure to those of your readers who enjoy the enthralling history of ancient Egypt. The presentation by Sir Stewart Abram of a permanent jewel bearing on its face the image of I-Em-Hetep to be the badge of office of the President of the Reading Pathological Society leads me to mention that at the foundation of the Nosocomia Lodge of Freemasons in 1909, a Masonic home so to speak for hospital officers, the founders perpetuated the name of this medicine god on the Past-Master's jewel. This jewel was designed by Mr. Chichele Nourse, F.R.C.S. Edin., the second Master of the Lodge, who in his design had engraved upon one side of the square the hieroglyphics signifying I-Em-Hetep, "He who cometh in Peace," amongst his other titles being those of "Master of Secrets" and "Scribe of Numbers."

With this history I am sure the Reading Pathological Society will allow the founders of the Nosocomia Lodge to share in the honour of having been the first in this country to recognise the claim of I-Em-Hetep to be regarded as the Egyptian Deity of Medicine.

I am, Sir, yours faithfully,
Richard Kershaw.

Central London Throat, Nose and Ear Hospital,
Oct. 20th, 1925.

*** Most fascinating and instructive reading with special reference to I-Em-Hetep (or Hotep) will be found in the Harveian Oration delivered in 1904 by Dr. Richard Caton, entitled The Medicine and Medicine God of the Egyptians (The Lancet, 1904, i., 1769). We reproduced (1906, i., 855) two photographs of a statuette of this deity from the collection of Signor G. Dattari, of Cairo.—Ed. L.

PITCAN PATENT BELTS.

We have received from Messrs. Carew, Ltd., 47, Lower Belgrave-street, S.W., samples of abdominal belts, intended to reduce undue bulk, support the figure, and correct the results of ptosis, while they may also be used as aids in cases of hernia and conditions resulting from undue strain. The belts, which are well ventilated, are made of a strong durable material and are fitted to the body by means of laces and straps. The firm works, we are informed, only under the orders of medical men and our readers may find the address useful.

SNAKE POISONS.

Dr. A. do Amaral, of the Serum-therapeutic Institute, Sao Paulo, Brazil, has brought out a little book entitled "A General Consideration of Snake Poisoning and Observations on Neotropical Pit-vipers." (Harvard University Press. London: Humphrey Milford. 1925. Pp. 64. 16 plates. 10*s.* 6*d.*) The first part gives a general account of snake poisons, their action and remedies; it is brief and without any bibliography, and does not add much to previous accounts, such as Prof. C. J. Martin's article in Allbutt's "System of Medicine." This is followed by five papers on the diagnosis and variation of snakes of the genus *Bothrops*, useful, no doubt, to specialists, and beautifully illustrated with coloured and plain figures of the dorsal markings. Apart from their morphological interest these plates might be studied with advantage by those in search of new colour designs.

A CENTURY OF MARINE HISTORY.

The evolution of the sailing ship and the steam ship is of interest to medical men because the "sea voyage" is a well-recognised and often effective method of treatment. For this reason we call the attention of our readers to a well-printed and well-illustrated book[1] of some 80 pages which has been privately published in commemoration of the centenary of the Aberdeen S.S. Line. The compilation of the book has been entrusted to the well-known writer Mr. L. Cope Cornford, who in telling the story of the progressive development of the Aberdeen Line incidentally indicates how the proud position of British shipping to-day can be traced to the foresight, courage, and industry of men like George Thompson, founder of the Aberdonian venture in 1825. Among the fine illustrations of the company's vessels are the *Childe Harold*, 116 tons, one of the earliest of the fleet, and the s.s. *Sophocles*, 12,361 tons, one of the latest, with greatly improved passenger accommodation, and the contrast between the brig and the modern liner tells better than words the progress made in 100 years. The present fleet now sail regularly to and from London, Portsmouth, Tenerife, Cape Town, Melbourne, Sydney, and Brisbane. The same steamship line also issue a small illustrated brochure in which the story is told more briefly.

CONISHEAD PRIORY HYDRO.

Conishead Priory was founded during the reign of Henry II., and is situated two miles from Ulverston, by the shores of Morecambe Bay. It was dismantled by Henry VIII., and as a residence it passed through the hands of many famous families, notably the Braddyls, before being acquired as a hydro in 1878. The fine buildings, the beauty of the site and its proximity to the Lake District, combine to make the hydro attractive, and the directors have now newly furnished and decorated it throughout. There is an 18-hole golf course at Ulverston and hard and grass tennis courts in the grounds; dancing is provided for, and it is intended that the place shall be an ideally comfortable winter residence. The hydropathic department was reopened on Oct. 1st, under the direction of Mr. John Wishart, M.D., D.Sc., and contains electrical and other equipment. Sea-water is pumped up daily from Morecambe Bay for bathing purposes, and a new Conishead Priory health course will be given during any four weeks of the winter season at a minimum cost of 20 guineas, exclusive of medical fees.

THE LATE MAJOR-GENERAL SIR HARRY THOMPSON.

To the Editor of The Lancet.

Sir,—A wish has been expressed by relatives of the late Major-General Sir Harry Thompson, K.C.M.G., C.B., D.S.O., late R.A.M.C., that his services should be commemorated. They will contribute to that end. Knowing that, in addition, there are many of his friends (civil and military) who desire to join in some material tribute to his memory, I venture to ask your kindly aid in publishing this appeal for funds to this purpose. The decision as to the most suitable form for the memorial to take should, it is considered, be left in the hands of the Harry Thompson Memorial Committee, who will be guided by the sum collected and the wishes expressed by the subscribers. Subscriptions should be sent to Messrs. Glyn, Mills and Co. (Holt's Branch), 3, Whitehall-place, S.W., the treasurers of the fund, or to the undersigned. All contributions will be acknowledged.

I am, Sir, yours faithfully,
S. G. Guise-Moores,
Major-General.

Osborne House, East Cowes, Isle of
Wight, Nov. 1st, 1925.

UMBILICAL HERNIA.

To the Editor of The Lancet.

Sir,—I am in my eightieth year and have long suffered from an umbilical hernia, of about the size of an ordinary walnut on protrusion. I have consulted many of my London medical friends about it and they have all taken a great deal of trouble, recommending belts of various descriptions. The belts all get out of position after a little time unless they have perineal bands, which are an abomination. For several years now I have been in the habit of applying a cotton-wool pad covered with indiarubber over the hernia after first reducing it. The pad is kept in position with one inch wide strips of "ZO" adhesive plaster, made by Johnson and Johnson, New Brunswick, N.J., U.S.A., and I have found that this never irritates the skin and only wants changing once a fortnight, although I have a warm bath every morning. I enclose my card, and am, Sir,

Yours faithfully,
M.R.C.S.

Oct. 28th, 1925.

THE WINDOW WITHOUT A VIEW.

To the Editor of The Lancet.

Sir,—Recently I paid a visit at a charming house which had been built but a few years. Opening the gate leading from the road, a tasteful garden met the eye; and a path, paved with crazy stones, led to the old-fashioned door. The external architectural features were pleasing. Little turrets, circular windows, overhanging eaves, and tiled roofs all combined to form a pleasant picture. I was shown into a prettily furnished drawing-room, and later conducted by the lady of the house into a large study with a wonderful fireplace, and into other rooms well designed. Everything seemed just right. But no! There was something wrong. We sat down and our hostess said she would like my opinion of the roses in the garden just outside. I could not see any roses. I could not see any garden. The fleecy clouds floating in the blue sky were visible, but that was all. You ask "Why?" Because the windows were set so high. One had to stand up to see out. I was told the bedrooms and nursery had the same fault, and a platform had to be built for the children so that their heads could be above the window level. The value of plenty of light and air has never been recognised so clearly as at the present time. It is hoped that architects, besides making provision for an abundance of these, will give us a view. We don't want to live in a glorified prison.

I am, Sir, yours faithfully,
Medicus.

Nov. 2nd, 1925.

An Address
ON THE
SPECIFIC CHARACTER OF MALIGNANT NEOPLASIA,
WITH SPECIAL REFERENCE TO THE CONTROL OF CANCER FROM THIS STANDPOINT.

Delivered before the Academy of Medicine, Toronto, on Nov. 10th, 1925,

By W. BLAIR BELL, B.S., M.D. LOND.,
PROFESSOR OF GYNÆCOLOGY AND OBSTETRICS IN THE UNIVERSITY OF LIVERPOOL; GYNÆCOLOGICAL AND OBSTETRICAL SURGEON, ROYAL INFIRMARY, LIVERPOOL; HON. DIRECTOR, LIVERPOOL CANCER RESEARCH; HON. FELLOW, AMERICAN COLLEGE OF SURGEONS; HON. FELLOW, AMERICAN GYNÆCOLOGICAL SOCIETY; HON. PRESIDENT, GLASGOW OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

IN the whole range of medical science there is nothing of greater interest and importance than the control of malignant disease. Even so, and in spite of the fact that I have expended much thought and energy for 17 years in attacking this question, I find it necessary to summon all my courage to deal in words with a problem so difficult, so engrossing, so momentous, and, I may add, once so contentious. Those of us who enter the arena in the fight against cancer must do so unfettered, having purified our minds of all preconceptions and prejudices. At the same time we must avoid attaching undue significance to every little detail that comes to light as the result of our own work or of that of others; the winnowing of the chaff from the grain must be relentless and thorough.

Now, in regard to the problem of malignant disease, unfortunately there has been a tendency to consider each fresh and important observation as "the solution of the central problem," instead of merely as a step in that direction. For instance, supposing that an absolutely specific causal factor, effective at will, were to be demonstrated, it by no means follows that the cancer problem would be settled. I need not refer to the numerous instances in medicine of such failures; they are well known, and it is interesting to reflect that in many of them the position, unlike that of cancer, has been, or has appeared to be, comparatively simple.

THE CANCER PROBLEM STATED.

The problem of cancer can only be the complete understanding and control of that divergence from the normal, both from preventive and curative points of view. This, indeed, is the "central problem," whether scientifically or practically considered; this, and not every fresh quest after the so-called cause or causes of cancer.

The solution of every large problem—as of those of Euclid—is dependent on the correct application, step by step, of a number of related demonstrata that lead to the final proof. We have long been in possession of a sufficient number of isolated facts from which to elucidate the final solution, if only they had been properly sorted and placed in their true perspective—that is, if we had known how they should look when placed. This is the history of every scientific achievement. The whole question of malignant neoplasia is so complex, and the appreciation of the possible mechanisms concerned requires such a wide range of knowledge, that it is not difficult to understand how it comes about that most investigators have been content to stumble along after one issue, whereas Pasteur, if he had attacked the problem, would have tried to visualise first the complete picture; he would have formed a substantial working hypothesis.

If clear thinking were ever needed it is surely essential to the solution of this problem; yet, as the result of the limitations mentioned, the most important aspect—namely, the *specific process*, as I call it—has been neglected in the hunt for a specific cause, or for specific causal factors acting in conjunction. Still, it is the result rather than the cause, as I hope to show, that is important, for undoubtedly malignant neoplasia is a specific process, but that is not to say that because a process is specific the cause must also be. Those who ascribe specific processes to specific factors are on hazardous ground, for there is plenty of evidence that specific processes of a similar character to that we are discussing—such as the development of an ovum—may be induced by many inciting factors. Indeed, it might as well be argued that because warmth may be a condition necessary for such a change it is the specific agent, whereas it may simply be a condition of environment.

Those of us who are sceptical in regard to the idea that a single specific causal agent, or a combination of two specific causal agents or factors, is inevitably responsible for malignant neoplasia, are fortified by much positive evidence that such factors are numerous. Nevertheless, we are always ready to accept, as we have done in the past, evidence of a newly discovered agent, which is capable of establishing one or more of the conditions necessary for the development of malignant disease.

If it be granted, as it is by a majority of investigators, that the inciting factors of malignant growth are many, it is reasonable to avoid, as we ourselves have done, that aspect of the subject, leaving to others the compilation of an encyclopædia of causes, and possibly the discovery of a factor common to all, in order to concentrate our energies on the consideration of the *nature of cancer*, which appears to be a specific process in itself, and of far more importance than the character of the exciting stimuli.

THE NATURE OF CANCER.

To the biologist growth is a process which is fundamentally similar, whatever its direction, character, or result may be. Theoretically, growth should be continuous and immortal. Practically, it may be persistent or discontinuous, and it is inevitably mortal, in the ordinary sense of the word. Malignant neoplasia differs not at all from differentiated growth in these respects. It is impossible, therefore, to regard neoplasia of a malignant character without taking into account innocent neoplasia and normal growth.

Normal somatic and differentiated growth of the individual is due to intrinsic stimuli acting under the influence of many conditions of environment, both relative—that is, relative so far as one cell influences another which may be adjacent: for example, the formation of the ectodermic structures of the teeth and eyes in relation to the underlying mesoderm—and general, in that the whole metabolism of the body is correlated and adjusted by adaptation to the surroundings, and is perpetuated by heredity.

The development of an innocent neoplasm is similarly situated; and it is impossible to separate a benign growth from simple hyperplasia which arises in normal, healthy cells as the result of increased normal intrinsic stimuli or adventitious, extrinsic stimulation acting on *healthy* cells—that is, cells that are in function fundamentally normal.

In malignant neoplasia the same factors are at work, but the condition of the cells on which they act is different, and the difference appears, from the evidence at our disposal, to be that the cells in which the abnormal development occurs are *not healthy.*

If we consider for a moment the statements I have just made it becomes obvious that they are too general in regard to malignant neoplasia. The view that innocent neoplasia arises from healthy cells is clear enough; but simply to say that the cells from which malignant neoplasms originate are unhealthy is too vague without amplification. By unhealthiness of a cell I mean, then, that for some reason it is not functioning normally. Now, the functions of a cell are twofold: in the first place it has functions in respect of its own individual metabolism; and, secondly, it possesses properties and activities in relation to the body as a whole, of which it is a unit.

What, then, happens to and in a cell driving it to adopt an unnatural, malignant, course of life? A healthy cell does not do this, a dead cell cannot. There is, however, an intermediate state. The cell functions are impaired. Whatever causal factor, whether metabolic or extrinsic, can permanently impair the cell, without killing it, may be regarded as a predisposing cause or "exciting factor" of malignant developments. When a cell is damaged by X rays it either recovers, develops abnormally, or dies. When it develops abnormally we may regard it as a process which implies a struggle for existence.

To understand the nature of this process—the struggle to survive—we must go back to the beginnings of growth in the individual, study them, coördinate our observations with the known facts of normality and abnormality, and find if there is anywhere a clue to the divergence from the normal that may be regarded as, what I may perhaps call, normal malignancy.

It will be remembered that in the mammalian ovum, long before the formation of the embryo begins, the collection of cells, into which the fertilised ovum has developed, receives its nourishment from the saline fluid with which it is surrounded; but that this is soon insufficient for the needs of the mass, undergoing rapid division, a phenomenon not unallied to the struggle for existence. Some further and better supply of food is required, otherwise the ovum will die. In ordinary circumstances the blastocyst attaches itself wherever it may be at the moment necessity urges, and draws its nutriment from the maternal tissues.

In the human subject this process may be fraught with dangers of various kinds, not the least of which is the absence of the inhibitory factor which prevents the invasion of the trophoblastic cells exceeding the normal limit, and developing into an abnormally malignant process.

If I may do so, without wearying you, I will quote a statement already published in special and, therefore, not readily accessible journals, for it expresses briefly and completely our views of the nature of malignant neoplasia:—

> "Malignant neoplasia in the human subject, as I see it, is a biological atavism. There is a time in the development of the ovum when somatic cell-correlation and differentiation can hardly be said to exist, except potentially. At that early stage the trophoblast, of which the ovum is largely composed, is engaged in a struggle for existence; unless it can eat its way into the maternal tissues, the whole ovum will perish. The zygote possesses, therefore, the power of developing into cells of two types, the undifferentiated nutritive cells and the differentiated somatic cells.
>
> "Normally, when satisfactory attachment has been obtained, and the maternal blood-vessels have been eroded with dispersion of the circulating blood of the mother among the advancing columns of trophoblastic cells, the area in which the fœtus is to develop grows rapidly, and pari passu the activities of the trophoblast, so far as plastic and invasive properties are concerned, are gradually arrested. Thus it appears that, when the elusive factor in somatic cell-correlation becomes operative and ensures normal and differentiated development in the fœtus, the growth of undifferentiated, 'malignant,' epithelium of the chorion is stayed. It is the nature of this controlling factor that we are endeavouring to determine.
>
> "Should the fœtus die and the supply of somatic 'correlating secretion' cease at a critical time in the period of control, the chorionic epithelium, suddenly relieved of the inhibitory action of this substance, may develop into that most unrestrained and malignant manifestation known as chorion epithelioma.
>
> "The chorion, as I have indicated, has a nutritive function, and to the epithelium is assigned the task of seeking and finding nourishment not only for its own metabolism, but also for the correlated and differentiated somatic cells of the embryo, which in turn send a hormone, we may presume, to restrain chorionic activity once a large enough source of food-supply has been tapped.
>
> "In view of the method of implantation of the ovum in the human subject, and of the origin of chorion epithelioma, it seems reasonable to suppose that cells of somatic tissues, formerly normal, may through senility, injury, infection, and the other inciting and predisposing factors of cancer, slowly lose their power of obtaining or utilising nutriment, and, as the process of starvation is a slow one, adjust themselves to the altered and altering conditions by reverting to an earlier undifferentiated chorionic, nutriment-seeking type.
>
> "It is probable that every cell in the body has this potentiality of atavistic reversion to the nourishment-providing proclivities normally possessed in a special degree by the chorionic epithelium. Once started on the perverted course, there is no reason why the growth of dedifferentiated somatic cells should be arrested, for like those of chorion epithelioma, they are free of differentiated, somatic control." [1]

This is a definite hypothesis founded on the facts of development as they are known to us. It is impossible to go back further in our search for phenomena, associated with growth, that have a bearing on malignant developments.

We have endeavoured to bring fresh light to bear from various aspects of the problem, and we have tried to discover the physiological cause or causes leading to the arrest of the active functions of the chorionic cells, once they have fulfilled their purpose. It seems likely, of course, that the factors governing the differentiation of the somatic tissues of the embryo control the activity of the chorionic epithelium. There is, indeed, much evidence in support of this view, such as the invariable absence of a live embryo in association with chorion epithelioma. Yet a long series of experiments which I conducted, many years ago it is true, failed to confirm or to refute this view. I am inclined to blame the conditions or the conduct of our work for the negative result.

It will not be out of place to emphasise here a few facts of clinical and pathological importance that have a bearing on, and, indeed, lend support to the hypothesis I have endeavoured to develop, before I pass on to a consideration of the experimental and clinical confirmation that we have been able to secure.

It will be remembered that I have referred to the fundamental similarity of all growth processes, pointing out that the earliest ancestral cells—the trophoblastic—are of sheer necessity malignant in character, and that the most malignant type of growth of which we have cognizance is due to the uncontrolled, riotous behaviour of these cells. On the other hand, there are innocent tumours arising in the differentiated tissues of the body, apparently as the result of increased stimulation of normal healthy cells; in other words, hyperplasia occurs.

Then there are certain growths which appear to lie between the innocent and malignant; for example, papillary tumours of the ovary. How can we fit these into our scheme, which might on casual inspection appear to demand such a clear-cut line of demarcation between innocent and malignant neoplasia that the two could not exist in the same tumour? There is, as I have stated, a most essential difference between innocent and malignant neoplasia, apart from the inherent similarity of all growth processes; but this does not exclude the possibility of a malignant development in an innocent neoplasm, as may occur in the hitherto normal, differentiated tissues of the body.

It seems highly probable that, when such a change takes place, the cells of the tumour, previously innocent, have outgrown their blood-supply, or have suffered some other form of metabolic disturbance, with the result that, if necrosis does not occur, they may take on a malignant form of life. This change from innocency to malignancy is most commonly seen in growths of a "cellular type," as we describe them, whether epithelial or mesial in structure.

In passing, it is interesting to note that, just as al primary tumours, innocent and malignant, conform more or less closely to the kind of tissue from which they arise, so the structure of a malignant neoplasm developing in an innocent neoplasm resembles the tissue type of the latter; and it is this conformity that sometimes creates the difficulty of deciding whether a tumour is innocent or malignant.

In this connexion it may be said that the more nearly the structure of a malignant growth approaches that of the somatic tissue in which it is developed so much the less virulent is it. Those neoplasms that bear in their texture an appearance resembling that seen in an early phase of the normal development of the tissue in which they arise are most malignant. It is, indeed, axiomatic that the nearer to the trophoblastic phase the character of the neoplastic cell, the nearer will a growth approach in malignancy the intense degree exhibited by the unrestrained chorionic epithelium.

---

[1] Bell, W. Blair: Public Health, 1924, xxxvii., 217; Jou Obstet. and Gynæcol. Brit. Emp., 1925, xxxii., 1.

If the statements I have made are correct and the conclusions based upon them are sound, we are justified in regarding the malignant change as a process that is quite specific in character. It is hardly likely that, if the working hypothesis I have enunciated above had been a crude guess, instead of the result of the consideration and correlation of known facts, substantiation of our views would have followed in such generous measure as has been the case. To this I shall now refer.

CONFIRMATION OF THE HYPOTHESIS.

It is always advisable in seeking confirmation of any biological conception to approach the issue from as many directions as possible. This was foreseen when money was provided by a few generous laymen in Liverpool for the purpose of verifying or refuting my views; and as a result a staff of distinguished men, the heads of departments in the University, were invited to coöperate in the prosecution of this important inquiry under my direction. The harmony that has existed and the very intimate interchange of ideas, have, I venture to think, led not only to the output of most valuable original work but have also gone far to place the hypothesis enunciated beyond direct criticism. A considerable amount of work still remains to be completed and developed, provided the means are forthcoming to keep this organisation in being.

The scope of our research work has involved studies in physical chemistry, under the control of Prof. W. C. McC. Lewis; in biochemistry, which is, after all, chiefly physical chemistry, under the joint supervision of Prof. Lewis and Dr. R. Coope; in pharmacology and toxicology, under Dr. W. J. Dilling; in pathology, by Prof. Ernest Glynn; in animal experimentation, by Dr. H. E. Annett; and in the treatment of cancer in the human subject by a group of physicians and surgeons.

In three years about 50 private interim reports have been circulated by members of the staff to their colleagues, and some of these deal with several subjects. So far only four papers have been published, but a number are ready or being prepared for the scientific press. In many instances the lines of inquiry overlap or are dependent one on the other. Much of the work is of a highly technical character, and cannot be suitably described in a few general terms. I am unable, therefore, to do more at this time than touch upon some of the results obtained that supply direct confirmation of our hypothesis.

PHYSICAL AND BIOLOGICAL CHEMISTRY.

In an earlier paper I stated that it appeared probable that lead—a metal to which I shall have to refer at some length directly—has an affinity[2] for the phosphatides and other lipins; and that these substances are probably present in malignant growths in larger quantities than in normal somatic tissues. In a communication of Gye and Cramer,[3] based, it is true, on insufficient material and, therefore, on somewhat inconclusive evidence, the general statement had been made that the more rapidly growing a rat or mouse tumour the greater the phosphatide content. No comparison with normal or other tissues was made by these workers. Their statement was based on the examination of one slowly growing transplantable mouse tumour and one that was rapidly growing, and of one rat sarcoma of rapid growth. It was almost a matter of luck that this conclusion turned out to be correct; but it might easily not have been so, for the variations that occur in similar normal and malignant tissues are considerable, and only by averaging a large number of estimations can a true conclusion be reached. Alone, however, even this finding is not of any great value; it is the relative character of the phosphatide content of tissues that gives such estimations their great importance.

Prof. Lewis and his associates[4] concentrated their efforts in the first place on an experimental examination of the functions of phosphatides and cholesterol in relation to the permeability of the cell membrane. Stated briefly, it was found that whereas a high lecithin content favours an oil-dispersed-in-water variety of emulsion, cholesterol favours a water-dispersed-in-oil type. When, as in cell membranes, these are present together and in the conditions believed to exist—namely, that lecithin and cholesterol are dissolved in different phases, that is, cholesterol in oil and lecithin in water—then a high lecithin-phosphatide ratio would indicate a high degree of permeability of the cell membrane.

This conclusion reached, it became a matter of importance to determine the water, the phosphatide and cholesterol content of normal human tissues, and of innocent and malignant neoplasms *of the same tissues*, and, also, in view of the general hypothesis to make similar analyses of chorionic villi.

This laborious task has been accomplished, some 36 specimens being examined. The very striking results obtained are summarised in the following table :—

Human tissues examined.	Water.	Phosphatides.	Phosphatide-cholesterol ratio.
Normal tissues (ovary, body of uterus, cervix) ..	77·5	2·86	2·8
Innocent neoplasms (ovary, uterus) ..	80·8	2·94	3·4
Malignant neoplasms (ovary, body of uterus, cervix) ..	81·6	4·4	3·6
Chorionic villi ..	89·9	6·84	4·7

In regard to these figures it should be stated that in a general way it is impossible to separate cancerous cells in malignant neoplasms from the supporting and surrounding normal tissues. If cancerous cells are mixed with normal tissues in the proportion of, say, 50 to 50—a figure that would undoubtedly favour the normal tissues—the values for malignant tumours would approach more nearly those for chorionic villi, which also contain a core of connective tissue that may have reduced the value of the figures standing to their credit. In short, chorionic epithelium and malignant cells in all probability have values in regard to the phosphatide content and phosphatide-cholesterol ratio not less than three times that of normal tissues and innocent neoplasms, and also a much higher water content.

Now, as we have seen, permeability of the cell membrane is associated with a high phosphatide value and a high phosphatide-cholesterol ratio. Further, a high water content is actual evidence of permeability, and permeability is favourable to rapid growth. These are the essential features of malignant neoplasia, and they are most noticeable in connexion with chorionic villi, which in the early stages of development are entirely, or chiefly, composed of chorionic epithelium.

---

[2] "Although I have suggested that the rôle played by lead in the phenomenon of arrested growth depends on a direct chemical reaction between lead-ion and phosphatides, we must not overlook the possibility that lead may act in other ways; for example, by the inhibition of enzyme action in relation to growth. The distinction between these effects, however, may not be so great as appears at first sight, since such a function of lecithin as, for instance, that of an oxygen carrier, might indirectly affect enzyme action."—THE LANCET, 1924, i., 267.

[3] Bullock (Gye), W. E., and Cramer, W.: Proc. Roy. Soc., B, Lond., 1913, lxxxvii., 239.

[4] Corran, J. W. and Lewis, W. C. McC.: Biochem. Jour., 1924 xviii., 1364.

Here, then, is unassailable confirmatory evidence of the views already expounded.

INHIBITION OF NORMAL GROWTH.

We have conducted investigations on several lines to test the effect of various substances on cell growth.

Vegetable Growth.—J. Patterson and the present writer[5] have observed in the case of hyacinths that, if the bulbs be immersed in solutions of lead, a graded effect in the growth of the roots can be obtained, according to the strength of the solution; and with solutions so strong as 1·0 per cent. the subsequent growth of the plant is almost entirely inhibited. It is, too, of remarkable interest that, if the bulbs used for experiment be dried and kept in the ordinary way until the following year, and then be placed in ordinary tap-water, they repeat exactly the phenomenon of arrested growth seen the previous year when they developed in lead-poisoned water.

A chemical examination of dried bulbs that have developed in lead solutions reveals the presence of lead. It is obvious, therefore, that the lead has become bound up with or has affected some body of importance to the normal growth process, whether of the cell membrane or the cell itself, and that even a year later limited growth alone is possible. It has been stated by various observers that seeds are rich in phosphatides, and there is little doubt that the same high proportion should obtain in bulbs, but we ourselves have not made estimations.

This work was carried a stage further by the investigation of the effects of other metals on the development of hyacinths. The ions of copper, zinc, and calcium were tested, and were found to produce certain effects on growth; but these were not really comparable with the effects of lead. Zinc and calcium appeared to be very toxic in the stronger solutions —that is, solutions containing from 0·001 to 1·0 per cent. of the metallic salt. Root growth was practically absent, and in only one case did flowering occur. In weaker solutions the root growth and flowering were unaffected. The same results were obtained with calcium salts. Copper, however, was extremely toxic, and in strengths of copper as low as 0·000 001 per cent., growth of the plant was entirely prevented. It appears likely, therefore, that zinc and copper are directly poisonous, and have no true graded effect in various solutions; they appear either to kill or not to interfere with growth at all. Calcium probably acts by reducing permeability of the cell membranes.

Dr. W. J. Dilling has conducted experiments of a similar character in regard to the germination of seeds (mustard and cress) and obtained somewhat similar results.

Animal Growth.—Dr. Dilling and his fellow-workers have conducted an important series of investigations on the development of frogs' eggs, on the subsequent growth of the tadpole, and on the growth of fish, when placed in water containing the salts of certain metals. He summarises the experiments on frogs' spawn and tadpoles as follows:—

1. *Beryllium.*—Non-toxic.
2. *Zinc.*—Does not arrest the development of frog spawn, but is either lethal to or delays the growth of tadpoles.
3. *Thallium.*—Does not arrest development, but is fatal to tadpoles.
4. *Copper.*—Does not arrest development, but further growth is checked at or about birth. Slows subsequent growth of the tadpole or is fatal to it.
5. *Thorium.*—Development arrest, but to a less degree than lead. No arrest of growth of the tadpole.
6. *Lead.*—In solutions of N/10,000 and stronger, lead completely arrests the development of eggs and checks the growth of the tadpole.

In connexion with the action of lead it may be stated, therefore, that in its effect it is much more definite and comprehensive in its selective specific effect on all growth than is the case with any other metal; indeed, it is the only metal that arrests development of the ovum, and stunts growth subsequently.

In connexion with the action of lead on the tadpole, I cannot refrain from quoting an interesting statement from a report of Dr. Dilling:—

> "The second point of interest noted was that arrest of development almost invariably resulted when the egg was at the reniform stage, which corresponds with the late gastrula stage of the embryo, and it was also observed that, if the embryo passed this stage, it generally progressed to hatching, even if it then succumbed. At the late gastrula stage, when these embryos died, the hypoblast is being formed at the expense of the yolk cells which later form a heaped-up mass on the ventral wall of the archenteron to be finally absorbed a day or two after hatching, by which time the mouth has opened. In view of the suggestion of Blair Bell (THE LANCET, 1924, i., 267) that lead arrests growth by a chemical reaction between the lead ion and such a phosphatide as lecithin, the fact that the yolk cells are rich in lecithin must be borne in mind. It may be that lead by combining with the lecithin in the yolk cells arrests by its toxicity further development of the hypoblast, and that this leads to death of the embryo. Presumably, on this theory the embryo would be most vulnerable if the lead reached it before the yolk cells were finally covered by epiblast, that is, just before the stage at which the embryo becomes ovoid or reniform. If, however, the lead does not reach the embryo until the yolk cells and yolk-containing hypoblastic cells are completely protected by the epidermal layer of epiblast, it is reasonable to expect, if Blair Bell's theory that the lecithin is the medium through which lead arrests growth, that the embryo would probably survive and develop to the tadpole stage, and this is, in fact, what has been observed. Then at the tadpole stage, when it comes into direct contact with the poisonous solution, it may succumb by absorption of lead through the external gills or mouth. At present, these must remain as suggestions to account for the observed facts; further work may confirm or disprove them."

The observations on the growth of plaice in lead-poisoned water gave similar results; the growth and vitality of the young fish were reduced, and the effect persisted after removal of the plaice to a normal medium. Finally, it is well known that children poisoned with lead are stunted in their growth.

We have, then, a large series of observations on normal growth, all pointing to the important—I think specific—action of lead on the growth processes.

EFFECT OF LEAD AND OTHER METALS ON THE CHORION EPITHELIUM.

Dr. Hendry, Dr. Annett, and the present writer have published a paper[6] on this subject, giving the results of our experimental inquiry. It has, of course, long been known that in lead-workers abortion is extremely common. The cause for this has been attributed to hæmorrhages in the uterus. I suspected and found many years ago that the action of lead was due to a specific effect on the chorion epithelium, but owing to the war the work was stopped, and my results were not published.

In our recent experimental investigations we demonstrated that, in rabbits, lead alone of all the metals tested—namely, lead, thorium, thallium, and copper—has a specific action on the chorionic epithelium: coagulation necrosis is produced in the cells, and, as a result, abortion takes place. If abortion occur after the other metals it is due to hæmorrhages in the uterus.

If we recall for a moment the table concerning the water and phosphatide content of normal malignant and chorionic tissues we will realise the importance of the investigation I have just mentioned and its bearing on our hypothesis and the problem resulting from it.

ACTION OF LEAD ON MALIGNANT GROWTHS.

We have now reached the final issue. If my hypothesis concerning the fundamental similarity of all growth processes in animals is correct, and if we find a substance that will arrest or be lethal to all, and also shows an increasing degree of toxicity towards growing tissues in direct proportion to their rapidity of growth and malignancy—that is, to the water, phosphatide content, and phosphatide-cholesterol ratio—then surely we have arrived almost at the end of our endeavour.

---

[5] Bell, W. Blair: THE LANCET, 1924, i., 267.

[6] Bell, W. Blair, Hendry, R. A., and Annett, H. E.: Jour. Obstet. and Gynæcol. Brit. Emp., 1925, xxxii., 1.

Will our work stand the final test: Does lead arrest malignant disease in man? Here, indeed, is the crux of the central problem. I can assure you that in this respect also we have the fullest confirmation of all I have said. By "fullest" I do not mean that we can cure every case of malignant disease. We cannot; that, unfortunately, will never be possible, as all those who deal with the disease must know. In the cure we may sometimes kill. I have in mind two cases, the first that of a young man with diffuse sarcoma of the stomach, as proved by laparotomy and histological section. The treatment by intravenous injections of lead caused total liquefaction of the stomach, and he died with acute peritoneal symptoms. At the post-mortem examination Prof. Glynn could find no stomach, simply a mush of dead tissue. The second case was that of a woman with a large, rapidly-growing post-cricoid carcinoma. After treatment the entire growth became œdematous and she was suffocated. At the post-mortem examination it was found that the entire tumour had undergone acute necrosis.

Some would say, What further evidence than that is required? If it is, we have it in the fifty or so patients who are believed well, out of about 200, mostly hopeless, cases treated. We have not selected our patients in any way. We have treated practically all who have been sent to us. Many have died within a few weeks of their arrival, before treatment had been hardly more than just begun.

I know you will want to hear very much about our successes. In the next month or so these will be published in THE LANCET. However, I may perhaps risk wearying you and mention two, for we have been fortunate enough to make for them yesterday and to-day days of thanksgiving.

On Nov. 9th, 1920—five years ago yesterday—a woman was admitted to my maternity ward at the Royal Infirmary, Liverpool, for her confinement, which took place a few days later. She was suffering with an extensive, ulcerated carcinoma of the left breast with glands in the axilla. Operation had been considered useless six months previously by two of my surgical colleagues. The growth had been accelerated during pregnancy, as is usual in these circumstances.

I was looking for just such a hopeless case. A section was prepared from a piece of tissue adjacent to the ulcerated area, and intravenous injections of lead were given. Not only is the patient well to-day, five years and one day later, but also she has had two more babies in the interval, both of whom she has suckled at the breast that was affected.

For sentimental reasons of a different character I may tell you about another patient who is now 38 years of age.

This lady was sent to me over a year ago. She had submitted to an exploratory operation at the hands of another surgeon. He found the abdomen full of malignant growth, which he correctly diagnosed as sarcoma, and promptly closed his incision. When she came to Liverpool, thin and ill, I reopened the abdomen to obtain a piece of growth for section, for this had not been done at the former operation. I, too, found the entire abdomen involved. Intestines were mixed up in the growth, and the whole outlook seemed most serious. In ordinary circumstances she had a few weeks to live, for sections showed the growth to be a most rapidly growing spindle-cell sarcoma. Treatment with lead injections has led to a considerable decrease in the size of the tumour, while the patient has herself increased in weight by 21 lb., and is now in robust health and without a symptom. She has been married to-day—November 10th.

CONCLUSION.

I have undertaken to present to you some of the confirmatory evidence obtained by a band of fellow-workers, that the hypothesis expounded is not only correct in its essential particulars, but also from every possible angle, including that of the ultimate test, it appears to be—may I say—proven.

I set out to show you that malignant neoplasia is a specific growth process in that it is a reversion on the part of the starving cell to the nutriment-seeking proclivities of its ancestral type, the chorionic epithelium.

A comparison between the chemical constitution of different tissues in regard to the factors concerned in growth processes demonstrates clearly not only that malignant tumours are richer in this respect than the corresponding normal structures and innocent neoplasms of the same parts, but also that the physiologically malignant chorionic villi show even higher values than pathologically cancerous tissues. The chorionic epithelium is super-malignant.

In the search for a substance that will arrest or have a specific lethal action on cells which possess the chemical constitution associated with malignancy we have found only lead. This metal is specifically active in regard to the chorionic epithelium, to the cells of cancerous growth, to normal embryonic growth, and to mature cells rich in phosphatides.

Some day we hope that a substance, less toxic to the organs of the patient that are rich in phosphatides, and even more effective than lead in arresting and destroying cancerous tissues, will be found. If that should ever happen, and it is not unlikely, we shall have still further confirmation of our belief that causes are as nothing in comparison with the importance of the realisation that malignant neoplasia is a specific process of the nature, and subject to the control I have described.

Bradshaw Lecture

ON

GASTRO-JEJUNOSTOMY.

Delivered at the Royal College of Surgeons of England on Nov. 11th, 1925,

BY JAMES SHERREN, C.B.E., F.R.C.S. ENG.,
VICE-PRESIDENT OF THE COLLEGE; SURGEON TO THE LONDON HOSPITAL.

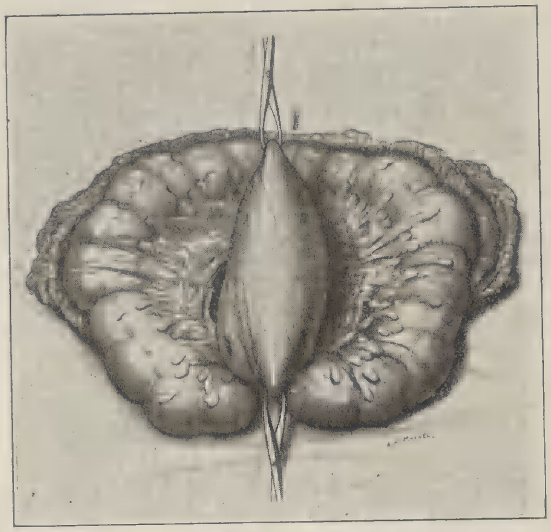
I MUST apologise for having selected an operation as my subject. I did so because of a firm belief that gastro-jejunostomy has had a more profound influence on abdominal surgery, and has done as much, if not more, for the good of the human race than any surgical procedure. On the other hand, carried out in unsuitable cases, or in suitable cases in an incorrect manner, it has, I regret to say, done as much, if not more harm, not only to the patient but to surgery in general than any operation. In suitable cases and correctly applied it has altered the whole outlook of countless chronic dyspeptics, and saved numerous valued lives for long service to the community. In addition to its widespread influence on abdominal surgery, the light it sheds on the ætiology of ulcerative lesions of the stomach and duodenum and on the cause of their symptoms was also a factor which convinced me, and I hope will convince you, that its study is eminently suitable for a Bradshaw lecture.

The present time seems opportune to review the matter, as from many sides we hear of its failure to cure conditions that are found curable by its aid in the hands of other surgeons. We have large and complicated procedures devised to supplant it, procedures that carry with them a mortality greater than that of the operation under discussion, and I venture to say that the death-rate of these would at least approximate to that of gastro-jejunostomy and to all its unsuccessful cases if they were considered as fatalities. Not even the most ardent advocate of these new operations would claim that every survivor was cured.

I should like first to draw your attention to a few points of historical interest. It was first carried out on Sept. 28th, 1881, in Vienna, by Anton Wölfer,[1] while assistant in Billroth's clinic. The patient was a male of 38, Michael Gold, surely a name to be remembered in the annals of surgery. He was suffering from pyloric carcinoma. Convalescence was uneventful and he was reported well four weeks later. The second case was done by Billroth himself on

Oct. 2nd, the patient being a man of 45. Bilious vomiting supervened the following day and continued until death on the tenth day. A post-mortem examination showed spur formation. Thus, the distressing post-operative symptom of regurgitant vomiting appeared early in its history. The course of abdominal surgery might have been different had this been the first case operated on. A surgeon must be thoroughly convinced of the soundness of his conception and its potentialities who would attempt it a second time in the face of such a result. The first successful gastro-jejunostomy in this country was carried out by Barker[2] for carcinoma of the pylorus on Jan. 5th, 1886. A day previously Morse,[3] assistant surgeon to the Norfolk and Norwich Hospital, had done a similar operation and both surgeons sutured the jejunum to the stomach before opening them. It was first performed in this country at the London Hospital by Reeves [4] on May 9th, 1885, on a woman of 40, with carcinoma of the pylorus. It is difficult from the brief account to follow exactly what was done, but it was a two-stage operation. I have been unable to obtain any information other than the short note published, and a careful search of the hospital records and operation books has not enabled me to trace the patient.

Fig. 1.



Showing the posterior surface of the stomach brought through the mesocolon and held vertically from the greater to lesser curvature, ready for the application of the clamp.

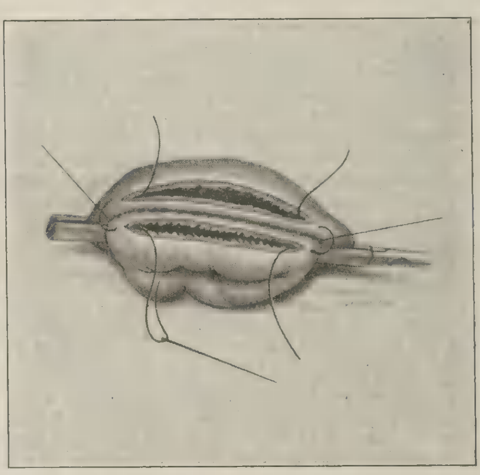
Carried out first for the relief of symptoms in irremovable carcinoma of the pylorus, it has been used in the treatment of most abdominal ills and, in cases that have come under my own observation, has been done or advised for the vomiting of pregnancy, disease of the spine and spinal cord, of the kidneys, and even of the middle ear and brain. It was not until 11 years after its introduction that Doyen[5] employed it in the treatment of chronic gastric ulcer. This is recorded in a most instructive paper. He was led to undertake the operation on the supposition that pyloric spasm played a large part in producing symptoms. The first patient was operated on in 1892 for the round type of chronic gastric ulcer, and was quite well at the time of his report three years later; during this interval he had operated on 14 other patients suffering from chronic gastric ulcer without pyloric stenosis. He was rapidly followed by others, and on March 22nd, 1893, it was first employed by Codivilla[6] in the treatment of chronic duodenal ulcer. This was in a male of 40 who was quite well five years later, and it was not until after this, to be exact on May 5th, 1898, that the second case was operated on by this surgeon. Surely an example of surgical patience we should all take to heart. If every operation were tested for a few years before being generally employed many procedures would be justly unknown to any but their inventors.

The first gastro-jejunostomy was anterior with a long loop, the jejunum being sutured to the stomach along a horizontal line with its proximal portion towards the pylorus (retro-peristaltic). In 1885 von Hacker [7] introduced the posterior operation, leaving a loop 20 cm. from the duodeno-jejunal flexure. It was 15 years later that Petersen [8] further improved it by shortening the loop and adopting the iso-peristaltic position of the jejunum introduced by Rockwitz [9] in 1887.

We thus see the international character of surgical work. This operation was conceived in Vienna and its first modifications came from the continent of Europe. Its extension to the treatment of chronic gastric ulcer we owe to the French, to chronic duodenal to the Italians. I do not think, however, we shall be claiming too much for the English-speaking races if we say it was brought to perfection by them, and the names of Moynihan and Mayo will always be associated with this.

It is impossible to give the many variations that have been advised and carried out from time to time, but the next great advance was the advocacy of the vertical position of the anastomosis by Sir Berkeley Moynihan. This was in an important paper entitled "Gastro-enterostomy and After,"[10] which was the first serious estimation of the value of this operation and its after-results. It contains these striking words: "I am an ardent and a sanguine advocate of this operation, than which I think there is none in all surgery more completely satisfactory." When carried out in suitable cases this is an opinion which I to-day still share. It is difficult to understand the very conflicting results reported as obtained after gastro-jejunostomy except on the supposition that they are due to want of appreciation of its indications and of the correct method of carrying it out; if success is to be obtained meticulous care is necessary at each stage. On the one hand, we have a paper written with the title "Gastro-jejunostomy as a Disease"[11]; on the other, we find from the statistics published from the Mayo Clinic[12] that they have a cure rate of 94 per cent. in duodenal ulcer after treatment by gastro-jejunostomy and of at least 85 per cent. after the same operation for the treatment of chronic gastric ulcer. No surgeon who knows the work of this institution, and most of us have been welcomed there, can doubt the accuracy of these figures.

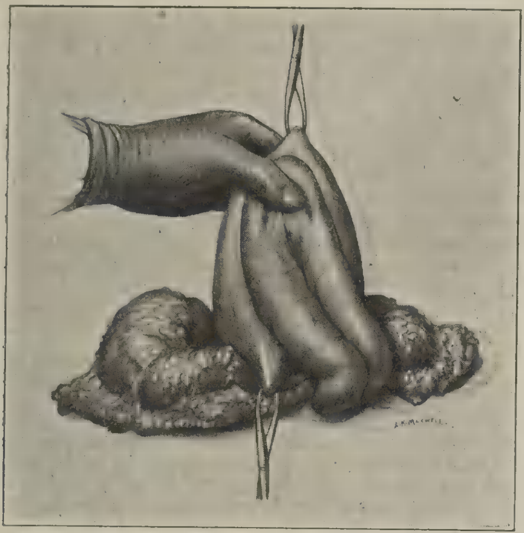
Fig. 2.



To illustrate the first insertion of the through-and-through sutures.

I should first like to describe the operations I carry out at the present time. The one which has given uniform success in my hands is the posterior retrocolic with vertical opening. The jejunum is taken at the duodeno-jejunal flexure and brought to the stomach so as to lie easily without tension on the one hand or looping on the other; the exact part therefore of the jejunum which is anastomosed to the stomach depends on the size and position of that organ. An opening is made in the transverse mesocolon immediately above the flexure, sufficiently large that its edges can be easily sutured to the stomach after the anastomosis has been made without causing deformity to it or the jejunum. The stomach just to the right of the cardiac orifice is clamped vertically from the greater to the lesser curvature (Fig. 1). If the operation is being carried out for a chronic gastric ulcer the anastomosis must be to its cardiac side; making it elsewhere is useless and the cause of many failures. This is even now not recognised universally, and sufficient stress has not been laid on this elementary fact. However the curative results are brought about, good cannot be anticipated when the opening is made to the pyloric side of the ulcer.

FIG. 3.

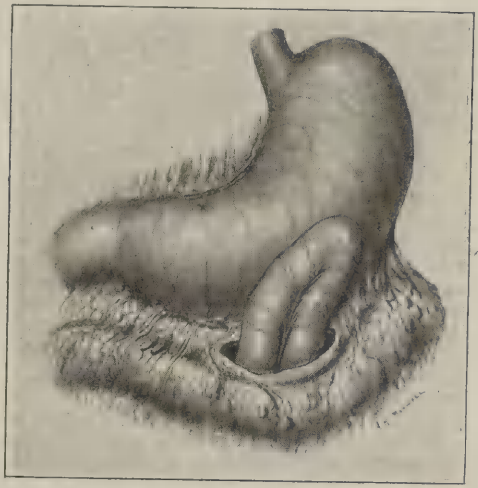


Showing the posterior surface of the stomach exposed and brought out through the gastro-colic omentum, the jejunum being brought to it in front of the colon.

The jejunum is brought to the stomach without a clamp and fixed to it at either end by stay sutures placed so as to secure its opening being exactly at the antimesenteric border and thereby avoid any rotation of the gut on its longitudinal axis. I find this much simpler to accomplish if no clamp is placed on the jejunum. Further, as I have stated before, it is possible that pressure of the clamp may in some instances be one of the causes of jejunal ulceration. No rule can be laid down with regard to the size of the anastomosis; it should extend when possible from the greater to the lesser curvature. This, of course, cannot be done if there is great dilatation; here, while falling short of the lesser, it should reach to the greater curvature. The viscera are then opened and the stitch through all their coats inserted. It is most important to get absolute apposition of mucous membrane so that I do not remove any that is redundant, and pay particular attention to the ends of the incision, uniting these first (Fig. 2). Nowadays the rare cases of gastro-jejunal ulcer are usually found at either end of the anastomosis, I believe due to failure of primary union of mucous membrane here, and it is for this reason that great care is necessary at these points. Before inserting the anterior layer of sutures I loosen the clamp and look for bleeding points. Finally the edges of the opening in the mesocolon are carefully united to the stomach at least half an inch away from the line of anastomosis. Where the mesocolon is very fatty, and the fact that the great omentum is in similar condition makes the posterior operation advisable, I carry this out as the first stage, so as to be certain that the oozing edges shall be well removed from the suture line and so avoid puckering or obstruction from adhesions later. Special care is necessary in dealing with these edges; all oozing should be stopped and the points I have stressed adhered to to avoid the possibility of late post-operative vomiting.

It may, however, be impossible or unwise to perform this retrocolic posterior operation on account of changes in the mesocolon, or adhesions of jejunum to its under surface. If the mesocolon is loaded with fat, or if it is shrunken and adherent to the posterior abdominal wall, operation through an opening in it may lead to severe late regurgitant vomiting. I am also very much averse for the same reason, when a considerable length of the jejunum is united to the under surface of the mesocolon, to separate it, as these adhesions may re-form and cause obstruction. I also think it is unwise to attempt the retrocolic operation if an opening of sufficient size cannot be obtained without dividing one of the vascular arcades. For several years I have carried out an antecolic posterior operation with a short loop in this type of case. The posterior surface of the stomach is exposed by an opening in the gastrocolic omentum, and the jejunum, brought in front of the colon at the splenic flexure, is united vertically to it (Fig. 3). In my hands this has given excellent results. When the posterior surface of the stomach is adherent and partial gastrectomy is unwise or not indicated, I do the anterior no-loop operation that I first performed in 1904 and published in 1907,[13] bringing the jejunum to the anterior surface of the stomach through the transverse mesocolon and gastro-colic omentum (Fig. 4). The opening is finally sutured around the anastomosis in the way I have described in dealing with the normal posterior operation. I have used Lukens' special catgut, No. 0, for suturing gastro-intestinal anastomoses for many years with uniform success.

FIG. 4.



Illustrating anterior no-loop gastro-jejunostomy, the jejunum being brought to the anterior surface of the stomach through the mesocolon and gastro-colic omentum.

I believe that many of the recorded bad results of this operation are due to the way in which it is performed. It is not enough to unite the jejunum to the stomach anywhere, the spot must be chosen as I have indicated, and the opening must be of sufficient size. I should like to illustrate published examples of methods of anastomosis which I do not think are best calculated to bring about the healing of ulcers and reduce gastric acidity. The first[14] is given as an illustration of normal gastro-jejunostomy (Fig. 5); you will see that the opening is horizontal, and that a considerable loop is left. The second is from a paper, unfavourably criticising this operation in the treatment of ulcer of the lesser curvature (Fig. 6). I agree that the type of operation here figured [5] is not the one most likely to lead to cure of the ulcer; it is horizontal and does not reach the greater curvature. To ensure healing the opening should be in the direction shown in Fig. 7.

INDICATIONS FOR GASTRO-JEJUNOSTOMY.

What are the indications for this operation? It is still necessary to state that it should only be carried out for the treatment of a lesion that can be seen, not on account of symptoms, however definite they may appear to be. In the first place, it is the operation that should be performed when surgical treatment has been decided upon in a case of chronic duodenal ulcer. It is rarely that any other procedure is necessary. The operation of gastro-duodenostomy has failed, in my hands, to bring about a satisfactory post-operative reduction of acidity and is more often followed by secondary ulceration. In my opinion duodenectomy has nothing to recommend it.

I should like to give examples comparing the pre- and post-operative fractional meals of patients with chronic duodenal ulcer, recently treated by gastro-jejunostomy and by gastro-duodenostomy. Figs. 8 and 9 are from a male patient operated on by me for chronic duodenal ulcer, after having had symptoms for ten years. With such a result one can certainly say that further trouble is extremely unlikely. Figs. 10 and 11 are from a female patient, operated on after 15 years history. There was a scarred ulcer constricting the first part of the duodenum, which was mobile and dilated. For this reason gastro-duodenostomy was feasible and was carried out with a wide opening. In spite of regurgitation, as shown by the presence of bile and a rapid emptying demonstrated by a barium meal, the chart shows great post-operative acidity. I shall be surprised if this patient does not develop further symptoms.

Gastro-jejunostomy is my operation of choice in chronic gastric ulcer when the ulcer is "free," without suspicion of malignancy, and the anastomosis can be made to its cardiac side. The statements in the paper to which I have just referred [16] are opposed to my experience of the results when the operation is carried out on the lines I have described. The following sentence occurs in it: "I have records of patients who got no benefit from it, and when the abdomen was opened after several years the ulcer still persisted." I also have records of this description, but they apply only to those patients in whom the operation was incorrectly performed, or for whom this treatment was unsuitable.

The following is an example:—

L. C., a male, aged 45, was admitted to the London Hospital under my care in December, 1924. He had had gastro-jejunostomy performed at another hospital nine years previously and had not been relieved in spite of the fact that his test-meal revealed an absence of free HCl and a total acidity of 16. Barium meal showed some delay in emptying, most of the meal being present at the end of an hour. At operation I found a large ulcer "free" on the lesser curvature. The gastro-jejunostomy was small, posterior, and near the pylorus, with no trace of secondary ulceration. After excising it I did my usual operation to the cardiac side of the ulcer. He did well, but died of another cause nearly three months later and I was fortunate in being able to obtain an account of the post-mortem. The gastric ulcer had absolutely healed and the anastomosis was perfect.

This is a very striking instance showing that it is useless to carry out the anastomosis to the pyloric side of the ulcer and illustrates a point I shall deal with later, that the post-operative gastric acidity has no bearing on the healing of the original ulcer. This patient obtained no relief after a gastro-jejunostomy performed to the pyloric side of the ulcer, even though it had brought about achlorhydria, but secured immediate relief and cure of the ulcer when it was done to its cardiac side.

Gastro-jejunostomy should never be advised in acute ulcers with hæmatemesis; it has no influence on this condition. In simple organic stricture of the pylorus, whether due to the cicatrisation of a duodenal ulcer or to any of the more unusual causes, it is the operation of choice. In hour-glass stomach in which the causative ulceration has healed it is of the greatest service, and if pyloric obstruction is present as well may necessitate a double operation. The results of double gastro-jejunostomy are excellent. The first, done 15 years ago, is, and has remained quite well, and all others have been equally satisfactory. That it is not often called for the following figures will show. I have operated on 135 cases of hour-glass stomach due to simple ulceration and in only seven has it been necessary. In the majority a penetrating adherent chronic gastric ulcer was present, indicating the need for partial gastrectomy. It is valuable in carcinoma which is irremovable and causes pyloric obstruction, but not otherwise.

RESULT OF THE OPERATION.

The mode of action and the result of the operation are closely related. The symptoms in chronic gastric and duodenal ulcer are due to spasm or irregular muscular action of the pylorus and pyloric portion of the stomach in duodenal ulcer, and of the body of the stomach in gastric ulcer and to the increased tension produced thereby. Who that has seen the progress of a case after gastro-jejunostomy for ulcer in those perhaps somewhat unusual instances where the pain is so severe as to necessitate the use of opium, and has noted the immediate post-operative relief obtained, will doubt this, and that the relief is due to the mechanical and not to the physiological or, as I prefer to call it, chemical effect of the operation. All who have watched on the screen the marked spasm in chronic gastric ulcer, and in addition their regular peristalsis in chronic duodenal ulcer, will realise that this is a factor which prevents healing. This spasm results in the meal passing at first chiefly by the new opening even in those cases, and they are in the majority, in which no organic stenosis is present. The effect of the operation is to cause more rapid emptying of the stomach and immediately to relieve gastric tension. Its action on the ulcer itself, therefore, is mechanical—that is, it gives the ulcer rest. I have yet to see failure of healing in suitable cases, and I have published many at various times in which I have had an opportunity of examining the stomach and duodenum post mortem or at second operation at long periods after the primary procedure. If healing were due solely to an alteration in the chemistry of the stomach chronic gastric ulcers would heal, even though the anastomosis were placed on their pyloric side and duodenal ulcers would not heal unless there was satisfactory change in gastric acidity. I have had to reoperate on several cases, the primary operation having been carried out by others, one of which I have just quoted, in which in spite of achlorhydria the lesser curvature ulcer was unhealed, the anastomosis being made to its pyloric side, and Ryle,[17] in his Goulstonian lectures, has published an example. It is my experience that chronic duodenal ulcers heal as the result of gastro-jejunostomy, even in those cases in which it does not bring about any profound change in gastric acidity. The operation brings about healing of the ulcer, whether gastric or duodenal, when carried out on correct indications.

On the other hand, from the patient's point of view, the permanent relief of symptoms, it is essential that gastric acidity be markedly diminished even to the abolition of free HCl to prevent fresh ulceration either in the jejunum or at the anastomosis should any infective focus be overlooked, or the mucous membrane fail to heal by first intention. But every patient in whom operation fails to reduce acidity does not develop further symptoms; it is only when

FIG. 5.

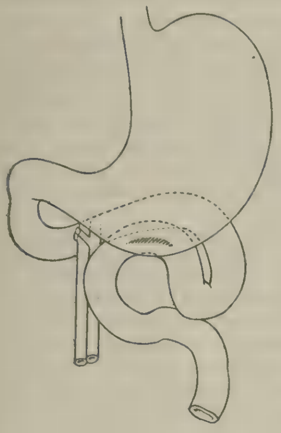


FIG. 6.

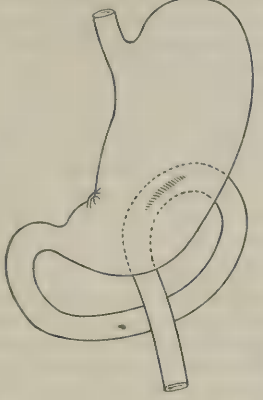

FIG. 7.

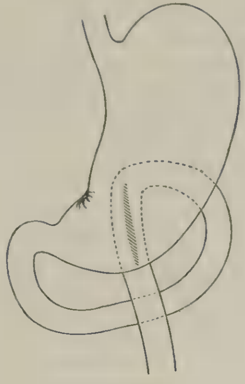

FIG. 12.

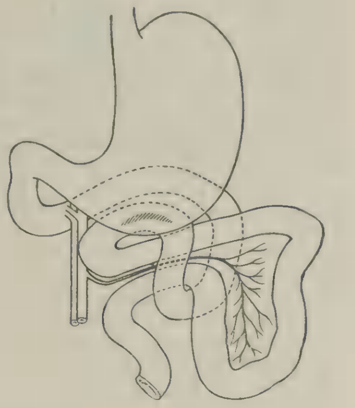

FIG. 8.

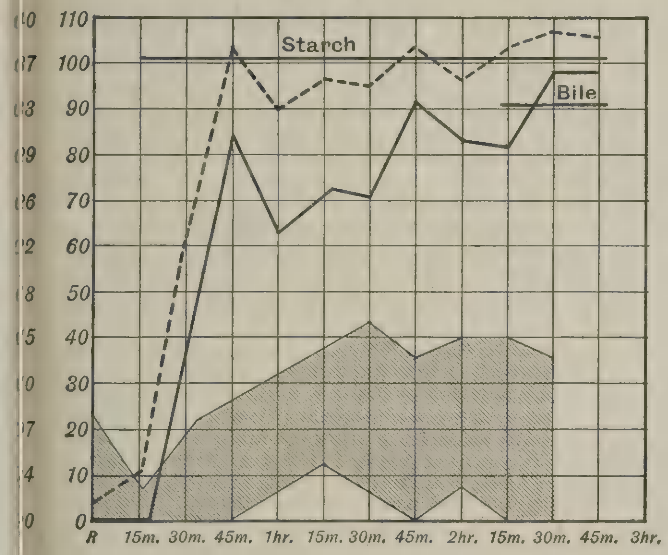

FIG. 9.

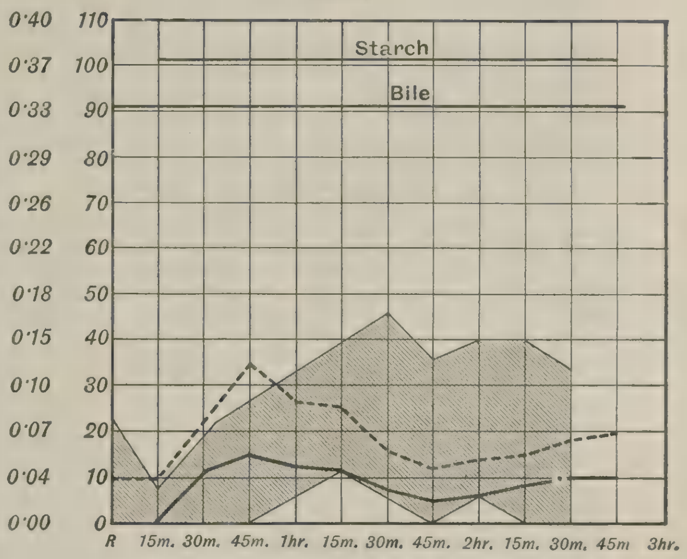

FIG. 10.

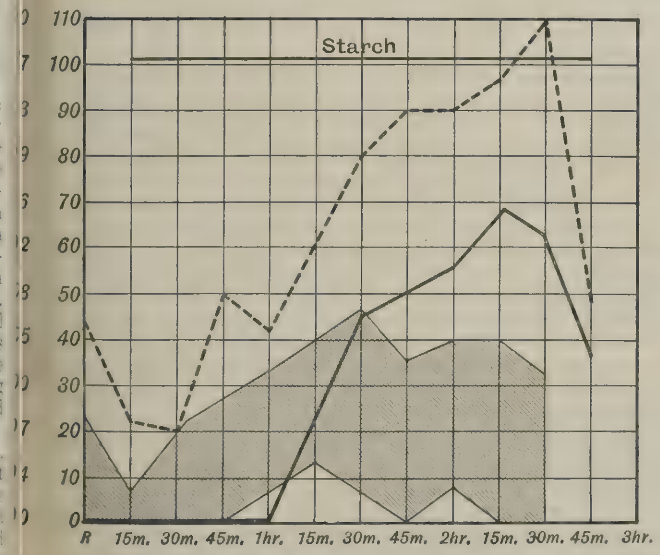

FIG. 11.

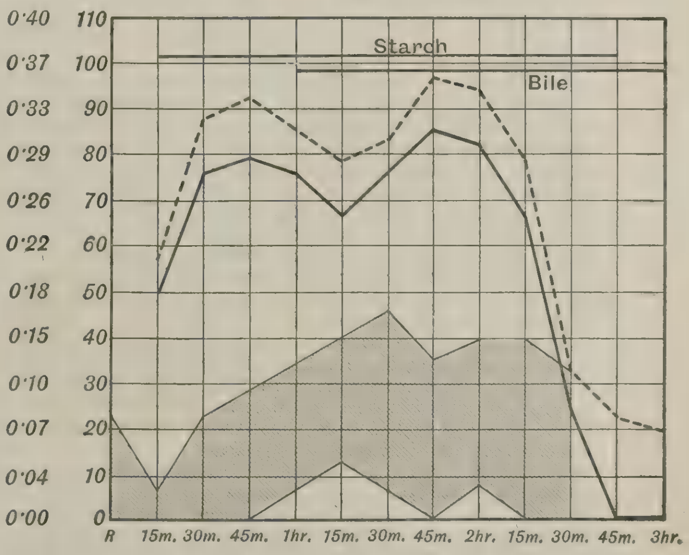

In all the charts the continuous line —— indicates free HCl; the broken line . . . . total acidity; the shaded area represents *the limits of free HCl* in 80 per cent. of healthy males (Bennett and Ryle). The figures at the left hand side of the charts indicate N/10 NaOH (per cent. HCl).

some other cause is present such as I have just mentioned.

Failure to reduce gastric acidity has no bearing whatever on the healing of the original ulcer; the operation is "mechanical" so far as this is concerned, "chemical" in its prevention of further disease. I am convinced that post-operative acidity is the predisposing cause of post-operative ulceration and that its great reduction is to a certain extent within our control; a large opening far removed from the pylorus brings about a greater lowering than a similar or smaller one close to the pylorus. I gave my reasons for this belief in my Hunterian lecture.[18] Recently Walton[19] has advocated a similar position for the anastomosis.

What are the causes of the post-operative lowering of acidity which almost invariably takes place after gastro-jejunostomy carried out for the treatment of chronic gastric ulcer, usually to as large a degree as after partial gastrectomy, and fails in some cases of chronic duodenal ulcer? I am certain that reflux of duodenal contents into the stomach is the principal factor. It has been satisfactorily proved that the pancreatic juice is the neutralising agent. In most cases of chronic gastric ulcer the anastomosis must from the necessities of the case be made well to the cardiac end of the stomach. But there is another factor besides that of the position of the stoma. The operation may be carried out on exactly similar lines in two patients of the same age and sex on the same day for the same condition with similar pre-operative meals. In one the post-operative meal reveals an absence of free HCl and a total acidity of 20, in the other one of 0·1 and 50. I shall have much more to say on this subject later, but I am convinced that it is in some way bound up with the use of the pylorus. It is possible that the production of secretin in the duodenum activating the pancreatic secretion may play a part, but I am inclined to the opinion that for the most efficient reduction neutralisation via the pylorus as well as the stoma is required. In support of the view that want of sufficient neutralisation is the cause of post-operative hyperacidity I will quote Bolton's[20] words on the subject:—

> "The essential cause of hyperacidity of the gastric contents is a deficiency in the neutralising process which regulates the acidity of the contents." And again, "The important point to note is that the condition hyperchlorhydria is the result of neuromuscular irritability of the stomach in which the pylorus plays chief part."

In the section dealing with gastric acidity following gastro-enterostomy, he writes as follows:—

> "Following gastro-enterostomy the secretion of gastric juice remains unchanged, any alteration in the acidity curves being due to neutralisation by regurgitation of intestinal contents through the stoma."

H. J. Paterson,[21] who has been an ardent supporter of gastro-jejunostomy and whose writings on the subject are classical, holds the reduction of acidity to be due partly to regurgitation through the stoma and partly to a diminution in the total chlorides secreted, and considers the action of the operation physiological, the result of this reduction of acidity, which he rightly deems necessary for the certain cure of the patient. But the ulcer heals after the operation correctly performed no matter what the gastric acidity, so that from the point of view of healing of the original lesion its action is not physiological.

Although failure to reduce post-operative acidity has no bearing on the healing of the original ulcer, it is of the utmost importance in the future welfare of the patient. I have on several occasions drawn attention to this, the last time in these words when speaking of secondary ulceration:—

> "If the operation permanently abolishes free HCl in the gastric juice, chronic ulceration does not occur. I drew attention to this in my Hunterian lecture, and, for reasons there given, consider it an important cause. I think there is no doubt that a large opening removed from the pylorus produces the greatest lowering of gastric acidity, and interference with the pylorus by exclusion or the presence of adhesions is an important factor in keeping up the post-operative acidity."[22]

I have revised the figures there given up to the end of June, 1925. Out of 195 personal cases of chronic gastric ulcer treated by gastro-jejunostomy in whom pre- and post-operative test-meals were given, in not less than 157 free HCl was abolished and total acidity markedly reduced, in all to below 30. In 26 it was greatly diminished, and in only 12 was it not reduced below normal. Of the duodenal ulcers, similarly brought up to date, 340 in number, in 206 there was absence of free HCl in the post-operative test-meal with a low total acidity, in 79 there was a satisfactory reduction, and in 55 there was little or no reduction. I wish to repeat again what I consider of the utmost importance—no case of secondary ulceration arose among those in whom the post-operative acidity was greatly reduced, and that the patients in whom further symptoms developed were from the group in which there was little or no reduction. It has been my experience that in many of the cases in which there is insufficient lowering of gastric acidity there is interference with the free action of the pylorus, and in these X ray examination shows that the barium meal is leaving chiefly or only by the stoma.

I am convinced that pyloric occlusion at the time of operation is a fertile cause of failure to reduce gastric acidity. Much has been written on this subject which it is difficult to reconcile. Donald Hunter[23] states that it had no effect on post-operative acidity, but on looking at Table VIII. I found these figures: 19 cases without pyloric occlusion, free HCl abolished in 10, remained high in 5, became higher in 4; 21 cases with pyloric occlusion, in only 8 was free HCl abolished, it remained high in 8, and became higher in 5. This is surely evidence that it affects unfavourably the post-operative reduction of gastric acidity. Apperley[24] studied 27 cases by post-operative fractional test-meals and was convinced that pyloric occlusion had no effect on gastric acidity, but that failure in reduction was due to a faulty stoma. I have already mentioned that a failure in satisfactory reduction may be due to the anastomosis being made near the pylorus; a small inefficient stoma will also be a cause, but neither is the sole explanation. In the majority of my own cases there has been no difference in the size or position of the new opening, and in very few did I have to make a note that for some reason the opening had to be smaller than I like and its position unusual. Investigation by X ray after a barium meal in those in whom there was little or no reduction showed that the stomach emptied as rapidly by the stoma as is usual after gastro-jejunostomy. I could discover no difference in this respect between those in whom free HCl was abolished and those with a high post-operative acidity.

Guy[25] examined by the fractional method 26 cases after gastro-jejunostomy. They were distributed as follows: gastric ulcer, 3; pyloric ulcer, 9; duodenal ulcer, 14. He argues that the reduction in gastric acidity is more marked in gastric ulcer because the pre-operative acidity is less and applies the same to pyloric ulcer, a misleading term that I should like to see abolished. Speaking of duodenal ulcer he states:—

> "Since duodenal ulcers are accompanied by such marked hypersecretion, a much smaller reduction in acidity after gastro-enterostomy is to be expected. It has been found invariably that a considerable degree of acidity exists after operation, and a study of the acid curves shows that a reduction to about half of the pre-operative acidity is the maximum that has been obtained. That is, the gastric secretion is now brought within the limits of normal acidity."

This is totally opposed to my experience of the condition. The figures I have quoted entirely disproved this, at least for my own cases. He traverses the view that pyloric exclusion has any bearing on the post-operative result in these words:—

> "The view expressed by Sherren that duodenal exclusion is the cause of post-operative hyperacidity is not borne out, as it has been demonstrated that a high acid level after operation is but the natural result of an excessive pre-operative hypersecretion and is not affected by variations in operative procedure apart from the provision of a stoma,"

but does not give the evidence upon which he bases the statement. Bonar,[26] in a study of gastric function before and after gastro-jejunostomy, also used the fractional method. In 14 cases of chronic gastric ulcer there was an absence of free HCl in 80 per cent., and in the remaining 20 per cent. a marked hypochlorhydria. In 33 cases of duodenal ulcer the fractional meal before operation showed a high acidity in an hour—that is, at the time corresponding with the Ewald meal. After operation he states that marked hyperchlorhydria was still present and that it was marked in three-quarters to one hour—that is, at the corresponding interval to that before operation. This again is not my experience. My results certainly do not bear out his statement that, "In the case of ulcers with high acidities gastro-jejunostomy does not cause to any extent a reduction of the acidity." I have notes of a considerable number of cases examined by the fractional method, though small when compared with those done by the single examination, the results at the hour both before and after operation correspond fairly well with those obtained by the single meal. I am still of the opinion that for diagnostic purposes the single test-meal before and after operation gives all the information necessary; certainly in hospital work it has given me results which correspond more closely to the clinical and operative findings than the fractional. Thus in the case illustrated by Fig. 10, in the fractional meal it will be seen that at the end of an hour there was no free HCl and a total acidity of 43, whereas the Ewald meal that I had given, as this was so unconvincing, showed free HCl 0·23 and total acidity 72, a test-meal corresponding with the condition found at operation. In a long experience of Ewald test-meals in chronic duodenal ulcer I have never had a result of this sort, but have had similar very puzzling discrepancies with the fractional meal. I have abandoned examination by this method except in an endeavour to throw light on exceptionally difficult cases. My medical colleague, Dr. Robert Hutchison, agrees that the "old 'single' or Ewald test-meal is to be preferred to the more modern 'fractional' type."[27] The investigations were all done in the London Hospital clinical laboratory under the supervision of Dr. P. N. Panton, without whose help these conclusions would have been impossible.

Ryle.[28] in his admirable Goulstonian lectures, deals in the third with gastro-jejunostomy and its sequelæ. Speaking of the post-operative reduction of gastric acidity he says that a case with deficient or low motility is more likely to respond to gastro-jejunostomy than one with increased motility; or in terms of the test-meal, a case with a steadily climbing curve is more likely to give a good result than one with a high abrupt peak of acidity and rapid evacuation. In my experience there is certainly no direct connexion between the time of emptying before and after gastro-jejunostomy and the acidity. He quotes me as saying we have yet to learn what is the cause of the failure to reduce post-operative acidity, but did not give my views on the subject that it is due to insufficient use of the pylorus and that for the most effective lowering of acidity it is essential that the pylorus be used as well as the new opening.

The results of the operation when done for chronic duodenal ulcer and picked cases of chronic gastric ulcer have been excellent. Failure to cure the patient occurs, apart from gross mechanical causes of which I shall speak later, or from overlooking lesions of other abdominal organs, only in that group in which there is insufficient reduction of post-operative acidity. Realisation of this is essential and improvement in our results will only come when our work is checked by this knowledge. Devine[29] states that "65–70 per cent. of gastro-jejunostomies for all types of duodenal ulcer were successful. This seems to depend chiefly on the ability of the operation to diminish greatly or abolish acidity." He adds, "Gastro-jejunostomy must therefore remain the basis of average gastric surgery," and considers that it should be, but is not, an ideal procedure. He mentions that the unsuccessful gastro-jejunostomies fell into a group in which there was an increase or little modification of acidity after operation, and that this was due to failure of alkaline regurgitation.

Success with this operation will depend on the care with which it is carried out along the lines I have suggested. Those of us who have obtained good results have been criticised. Pannett,[30] for example, speaking of those who claim 90 per cent. successes, says there is "obviously some radical difference in the manner of evaluation." I should rather say in the exact manner in which the operation is carried out. In a further paper[31] he gives the names of those with cure rates in the region of 90 per cent. Speaking of my own figures I have followed these cases up from the very first and have counted as "quite well" only those patients who have been perfectly well throughout; if they have any digestive complaints they may be included among those improved, but not among the 90 per cent. All patients are seen at 3, 6, and 12 months after operation and heard from yearly till after the third year. I shall give an example later. I have again brought the earlier cases up to date and confirm what I have said before, that the longer the cases are traced the better the result, and most of those who had minor troubles in the first year lost them later and had completely forgotten eight or ten years after that they had occurred. I can speak for the thoroughness of the follow-through method of my colleague Mr. Walton,[32] who has recently described it. The Mayo Clinic needs no defence from me. The results published in the paper from which my figures are taken[33] are better than those of four years previously, owing, I believe, to increased skill in carrying out the operation due to following up all the patients carefully and improving technique; several of the patients then not well are now well. Balfour's[34] figures in chronic duodenal ulcer are an eloquent testimony, 88 per cent. quite well among 1000 patients. Metraux[35] in the study of cases in Roux's clinic found that in 90 per cent. of the cases of chronic gastric or duodenal ulcer treated by gastro-jejunostomy alone a good result was obtained. Peck[36] wrote that simple gastro-jejunostomy properly performed is curative and adequate in the great majority of chronic duodenal ulcers, and that from 80 to 90 per cent. are completely relieved of their symptoms and remain well as they are followed from year to year. We cannot dismiss these figures as due to insufficient care in estimating results as Pannett has done, but rather look to the nature of the operation that others are doing and see if this will not account for their less satisfactory results. If the figures I have quoted from various writers of the failure to reduce gastric acidity after gastro-jejunostomy for duodenal ulcer are an index there is certainly a reason for its failure in many cases.

To sum up, gastro-jejunostomy carried out on modern lines will bring about the healing of all uncomplicated cases of simple chronic gastric and duodenal ulcer. Cases in which the floor of the ulcer is formed by pancreas or liver, or in which there is any suspicion that it is malignant, must be treated by partial gastrectomy. Cure of the patient—that is, complete and permanent abolition of symptoms—will be brought about in at least 90 per cent. of the cases, among the eight or nine not cured seven will be minor complaints, and not more than 2 per cent. secondary ulceration. When such a result can be brought about at a risk of less than 1 per cent. it is obvious that this operation has a permanent place in surgery. I have found no difference in the cure rate of those with organic pyloric obstruction, chronic duodenal ulcer without obstruction, or free lesser curve ulcers. I have obtained equally good results when I have been compelled to use my anterior operation. The first case was in December, 1904, and in this instance I was able to prove that the ulcer was healed at post-mortem 18 months later after accidental death. I have traced a woman operated on in January, 1908, now 74 years of age, without abdominal trouble. A male patient of 39 with a very indurated lesser curve ulcer operated on in July, 1913, remains quite well. I first carried it out in the treatment of chronic duodenal ulcer in a male of 48 on Nov. 11th, 1908. He had an indurated ulcer involving both surfaces of the duodenum; he is now, and has remained throughout the 17 years, quite well.

COMPLICATIONS.

We now come to the principal complications. They may be divided into: (1) Failure to produce healing of the original ulcer or its recurrence; (2) secondary ulceration; (3) intestinal obstruction including regurgitant vomiting; (4) late development of carcinoma.

Failure to Secure Healing or Recurrence.

(1) As I have many times stated I have never found a duodenal or gastric ulcer unhealed at a second operation or post-mortem when an efficient gastro-jejunostomy had been carried out in a suitable case, and my experience now extends to over 100. To prevent anyone thinking this is evading the issue I will state if the ulcer was free and the anastomosis carried out on the lines I have laid down. Where there has been chronic perforation with erosion of the pancreas or liver, a small part of the ulcer sometimes remained unhealed. They are cases in which I recognise that gastro-jejunostomy is not the ideal procedure, but even in many of these it has promoted healing. I was astonished recently on going over my old operation notes to find in how many, in which I had recorded that partial gastrectomy was the ideal operation but could not justifiably be done, the patient had remained absolutely free from all symptoms when traced for as long as 10 to 20 years.

The first case of this nature I operated on in which this note appears was a little over 20 years ago—a man of 33 with a seven years' history, which included two attacks of hæmatemesis. At the operation on Oct. 4th, 1905, I found a large saddle-shaped ulcer of the lesser curvature adherent to the pancreas and carried out posterior gastro-jejunostomy to its cardiac side. I traced him in the way in which I keep in touch with all the patients; I saw him three and six months after operation and heard in 1907, 1908, 1910, 1911, 1913, 1914, 1916, 1919, 1922, and saw him two months ago. He has never had any digestive complaint.

I cannot conceive of a better testimony to the value of the operation.

I have on several occasions found a chronic gastric ulcer unhealed at a second operation in cases in which the gastro-jejunostomy was done to its pyloric side; even if excision is added to this procedure and the gastro-jejunostomy done to the pyloric side of the excision wound, fresh ulceration is usual in the scar. Recurrence of the ulcer or failure in healing may occur in cases in which the gastro-jejunostomy opening has closed or become much contracted as the result of secondary ulceration. In the oft-quoted case recorded by Corner[37] of the fatal perforation of a chronic duodenal ulcer in a patient upon whom Sir Berkeley Moynihan had performed a posterior gastro-jejunostomy three years previously there was contraction of the opening. Corner stated: "There was no jejunal ulcer present; indeed, the gastro-enterostomy opening was very contracted." It is my experience that gastro-jejunostomy openings do not contract to any extent except as the result of marginal ulceration, and as, from the history, the patient had not been really free from symptoms this was undoubtedly the case. I would remark that the original operation was done in the early days in which marginal ulceration due to unsuitable sutures was by no means unusual. I can give a recent example which illustrates the two points, failure of healing or recurrence of the ulcer and closure of the gastro-jejunostomy opening.

A man at the age of 42 was operated on in 1915 by a surgeon, since retired, for a chronic duodenal ulcer with a history of 20 years' standing. Silk was used for the anastomosis. He remained quite well for 12 months and then began to get pain, which differed from that before operation by being in the lower abdomen. The attacks of pain were at first infrequent, but the intervals became shorter and the attacks longer, and when I saw him in February, 1925, he had had severe abdominal pain, which would wake him at night and for two or three years this had been in the upper abdomen. He was a thin man with an obviously dilated stomach. X ray examination showed that it still contained much of the barium meal at the end of seven hours and that little, if any, had passed by the stoma. At operation I found a large anterior duodenal ulcer. The gastro-jejunostomy opening was so small that it certainly measured no more than ¼ inch in diameter. My note says: "I have never seen an opening so contracted, it would have been possible to say that it had completely closed." I carried out posterior gastro-jejunostomy and he lost his symptoms at once.

In speaking of the development of fresh ulceration I have operated for chronic gastric ulcer ten years after gastro-jejunostomy for chronic duodenal ulcer and am able to show the specimen which is now in our museum.

In February, 1913, I operated on a woman of 43, who for 16 years had been having periods of pain after food with one attack of profuse hæmatemesis and melæna a year after the onset of symptoms. Her test-meal was 0·25 and 100. I found a large ulcer on the anterior surface of the first part of duodenum and did a gastro-jejunostomy nearer to the pylorus than I do now, and removed her appendix. Unfortunately no post-operative test-meal was given; at that time I did not have it carried out as a routine. She remained well for two years and then got an attack for which she kept her bed two weeks, a similar one in 1919, and again in 1923. Her barium meal report was: Penetrating ulcer lesser curvature towards cardiac end. Stoma normal. Duodenum functioning normally. Test-meal 0·10 and 35. At operation on June 8th, 1923, I found the duodenal ulcer healed and the gastro-jejunostomy opening perfect. Well to its cardiac side was an ulcer the size of a shilling, which had perforated and was adherent to the pancreas. I did a partial gastrectomy and she remains quite well. On examining the specimen the stoma was as large as the day I made it ten years previously.

In this case the ulcer was either overlooked by me at the first operation or formed later on the cardiac side of the anastomosis. It illustrates once again the uselessness of a stoma to the pyloric side of an ulcer.

Secondary Ulceration.

(2) Secondary ulcers are those which develop in the region of the anastomosis either true jejunal or gastro-jejunal. I still believe, in spite of Walton's[38] experience, that these are separate conditions, although we cannot differentiate them by their symptoms or their causation. Both are due to the action of gastric juice on tissue whose vitality is lowered. This may be from hæmorrhage, infection, or by the failure of union of mucous membrane exposing the underlying tissue. They occur in those cases and those only in which operation fails efficiently to reduce gastric acidity. I should like to repeat again that I have never known the development of secondary ulceration in any patient in whom operation has abolished or very greatly reduced the amount of free HCl in the gastric contents as noted in an Ewald meal. I should again like to emphasise its rarity in women and after operation for gastric ulcer; this I attribute to the infrequency of duodenal ulcer in this sex and after chronic gastric ulcer to the greater proportion of cases in which free acid is abolished and the total acidity is much lowered. In the unusual instances of chronic gastric ulcer with high acidity in which gastro-jejunostomy fails to reduce it there is a liability similar to that in chronic duodenal ulcer. The following is an example and illustrates several important points.

On July 10th, 1917, I operated on a male, aged 40, with the following history. He had five attacks of indigestion, pain late after food, not relieved by it but by occasional vomiting. In his last attack the pain waked him at night. In an attack a year previously he had been in hospital with hæmatemesis; test-meal 0·2 and 78. My own notes are as follows: Gall-bladder normal. Two very indurated ulcers on the lesser curvature, close to the pylorus. There were no outlying nodules and nothing definitely to suggest malignant disease, but had his condition been better I should have done partial gastrectomy. The jejunum was adherent to the under surface of the transverse mesocolon. I made my anastomosis nearer the pylorus than usual and found a considerable loop of adherent gut had been left between it and the duodeno-jejunal flexure. Appendix not removed. His post-operative test-meal—0·12 and 56—was unsatisfactory. I saw him on Sept. 3rd, 1917, and Nov. 4th, 1917, and heard on August 8th, 1918, and Dec. 30th, 1922, that he was in perfect health. He then began to get attacks of pain two hours after food, relieved by vomiting recurring every four to six months. He was admitted to St. Mary's Hospital, and I am indebted to Prof. Pannett for these notes: X ray examination showed delay in the pyloric antrum, but the stoma functioning. Unfortunately no test-meal was given. At operation a gastro-jejunal ulcer was found at the left lower margin of the stoma. The gastric ulcers had completely healed.

This is one of the last cases in which thread was used for the outer layer, and I had to resort to it owing to a shortage of Luken gut. The ulcer was in the usual situation for a gastro-jejunal—that is, at one of the extremities—and I attribute it to working out of the knot of the suture leaving an ulcer which could not heal on account of the high gastric acidity. It is extremely uncommon for symptoms to recur after a lapse of over two years, even after the use of silk or thread for the outer layer of sutures and this is only the second case I have seen. It is an apparent exception to the "rule" that patients free from symptoms for two years do not develop secondary ulceration, but it is obvious that this could not apply to ulcer directly due to unabsorbable suture material in the outer layer as it may take years to work its way out, and if this occurs in a patient with normal or increased gastric acidity the formation of a chronic ulcer is probable.

There are thus, I believe, two factors. One is the failure to reduce gastric acidity. If this remains high then an area of lowered resistance, the result of undiscovered infection in the mouth or abdomen, or of hæmorrhage from puncture of a vessel during suture or bruising from the use of a clamp, may bring about ulceration in the jejunum. If, either from faulty suturing or unabsorbable material being used, the mucous membrane of the anastomosis does not heal by first intention, or, if healed, a suture or its knot works its way out, then gastro-jejunal ulcer may occur. The last true jejunal ulcer upon which I operated was last December. The history is so characteristic of the condition that I must quote it.

In November, 1920, I operated on a male of 45 for duodenal ulcer with a typical history extending over ten years. His barium meal showed the ulcer and his test-meal was 0·23 and 90. At operation: Gall-bladder normal, large ulcer anterior surface first part. Posterior gastro-jejunostomy carried out without difficulty and a fibrotic appendix was removed. His post-operative meal was 0·2 and 81. He remained well for five months only and then began to get pain late after food in the epigastrium and left iliac fossa. I took him in for treatment a year after operation with relief for a time; his test-meal was then 0·13 and 62. The attacks became worse, so that I operated last December; his test-meal was 0·19 and 62. The duodenal ulcer had healed; there was a chronic ulcer in the jejunum immediately distal to the anastomosis adherent to the colon. I excised it, closed the opening in the stomach and jejunum, and carried out pyloroplasty, with the result that his post-operative meal 14 days later was 0 and 33 and the stomach was empty in 25 minutes. He remains well.

The case I quoted last year[39] as an example of jejunal ulcer after gastro-jejunostomy was treated by partial gastrectomy on June 21st, 1921. He remained well for nearly two years and then began to get pain two hours after food. I admitted him again on Dec. 29th, 1923, and found that his gastric acidity was 0·09 and 40. He lost his symptoms while in bed, but ten months later developed diarrhœa and fæcal vomiting, and at operation on Nov. 21st, 1924, I found a jejuno-colic fistula. In this instance I had been unable to restore the lumen of the jejunum so as to carry out the usual partial gastrectomy, as I endeavour to do in cases of this type, and had to do a T-shaped anastomosis of jejunum to jejunum below the gastro-jejunal one, and this accounts for the recurrence.

The condition of secondary ulceration in my own practice is getting rarer with each series of cases. With regard to malignancy supervening on a gastro-jejunal ulcer, I have yet no definite case, but I still consider it a remote possibility.

To sum up, secondary ulcer is the result of failure of the gastro-jejunostomy to lower gastric acidity. But this post-operative excess of acid is not in itself enough, as we see that the ulcer for which the operation was performed heals. There must be some lowering of resistance, either a gap in the mucous membrane from faulty suturing, removal of too much mucous membrane, working out of unabsorbable suture, hæmorrhage, or infection. Their incidence can be lessened even if the condition cannot be completely abolished by careful dealing with all infection and scrupulous attention to all the details of the operation.

There is to my mind no doubt of the necessity for avoiding pyloric exclusion. A case published by Frankau[40] shows its effect experimentally. I am much indebted to him for further notes on the case which enabled me to trace the patient to his original surgeon and obtained fuller details.

In 1914 a man of 29 was operated on for duodenal ulcer. His test-meal was 0·2 and 76, but no post-operative meal was given. Symptoms recurred in nine months, and he was admitted to St. George's Hospital after several severe attacks of hæmatemesis and melæna. His test-meal then was 0·26 and 82. At operation an unusual condition was found, in that there was still a chronic duodenal ulcer present, but there were no signs of ulcer at the anastomosis or in the jejunum. The pylorus was clamped and divided. He remained well for 14 months, and then had abdominal pain, diarrhœa, and vomiting. He was reoperated upon and a jejuno-colic fistula was discovered.

The unfavourable result with pyloric exclusion is borne out by the experience of others. Haberer's[41] figures are instructive; among 265 cases of gastro-jejunostomy there were three cases of jejunal ulcer, but in 71 cases in which pyloric exclusion was added in the treatment of duodenal ulcer no less than 14 developed jejunal ulcers. Kummell[42] had previously pointed out its frequency under these circumstances. Finsterer,[43] who is now an ardent advocate of wide partial gastrectomy in the treatment of duodenal ulcer, writes that Haberer had 25 per cent. secondary ulcers with pyloric exclusion and posterior gastro-jejunostomy. Norman Dott[44] demonstrated experimentally that chronic peptic jejunal ulcer is the constant sequel of gastro-jejunostomy with pyloric exclusion in dogs. Von der Hütter[45] found in his experiments on dogs that jejunal ulcer did not develop in those cases in which the pylorus was patent, but that it was produced when pyloric exclusion by von Eiselsberg's method was carried out. Gussio,[46] from a study of cases of jejunal ulcer, came to the conclusion that its development is favoured by impermeability of the pylorus. Enderlen, Freudenberg, and von Redwitz,[47] as the result of experimental investigations on dogs, came to the conclusion that pyloric exclusion should be abandoned.

As we know that jejunal ulcers only arise in those cases in which there is failure to reduce post-operative acidity it seems to me obvious that interference with the pylorus is one of the causes of this. In 1921[48] I stated that most of my cases of jejunal ulcer occurred in those patients operated on between 1911 and 1913, when I carried out pyloric exclusion, and my observations since then on cases in which from any cause there was interference with the free function of the pylorus confirms this as there was a failure of post-operative reduction.

Ryle[49] states, "There is a greater liability to gastro-jejunal ulcers in young adults and in cases with a short dyspeptic history." As this was not my experience I have put it to the test so far as possible. I took all the cases of secondary ulcer, whether jejunal or anastomotic, that I have operated on, 44 in number; the youngest was 25 at the time of the original operation, the oldest 55, and the average age was 41·7. I then took the same number of consecutive cases of chronic duodenal ulcer, operated on over two years ago; the youngest was 17, the oldest 62, average age 40·4. I then took duration of symptoms before operation in the cases that developed secondary ulcer; the average was ten years, in the consecutive cases the average was 9·5. The number of cases is small, but there is an astonishing correspondence in the two series sufficient, I think, to controvert Ryle's statement. Such varying estimates have been given of the frequency of secondary ulceration that it is difficult to discuss. In a recent paper Lewisohn [50] states that in a series of 68 cases re-examined 4–9 years after gastro-jejunostomy, 34 per cent. suffered from gastro-jejunal ulceration. As in a following paragraph he states, “ Gastro-enterostomy does not reduce the hyperacidity even after many years,” we seem to have the reason for this high percentage. My experience coincides with that of the Mayo Clinic that it is met with in less than 2 per cent. of the cases. Although in large series done in the one clinic the percentage is between 1 and 2 per cent., I still believe that even this can be lowered and should not like to think, as suggested by Walton,[51] “ that the failure of the acid to fall in these gastro-jejunal ulcer cases may be due to an anatomical variation, the acid-producing cells in a certain number of duodenal ulcer cases (about 2 per cent.) being more widely distributed over the gastric surface and thus being less affected by the gastro-enterostomy.” To me this is tantamount to saying we can do no more.

It must be remembered that excision of the ulcer with pyloroplasty or even doudenectomy does not protect the patient from secondary ulceration, and I suspect that its frequency is greater after both these, as pyloroplasty does not usually bring about so great a reduction of gastric acidity, and duodenectomy, like resection of gastric ulcer, will probably be given up on account of recurrence. Mann and Kawamura [52] found that after complete duodenectomy in dogs jejunal ulcer developed in two cases out of ten leading to perforation at 515 days after operation in one, and in the other it was found post mortem 383 days after.

None of the arguments from the secondary ulcer standpoint that have been brought against gastro-jejunostomy seem to me to be valid. It is the most serious drawback, but it is one that we are getting to understand as we realise that what is necessary is not merely a mechanical opening, but control of acidity. In many of the cases of failure to cure the patient other lesions in the abdomen have been overlooked, and I have had to remove the gall-bladder and appendix in these patients on many occasions after the failure of gastro-jejunostomy to cure all their abdominal ills. This should, of course, always be done if practicable at the time of the original operation and as part of the treatment in removing all possible sources of infection.

Intestinal Obstruction and Regurgitant Vomiting.

(3) The bugbear of the early operations, that of regurgitant vomiting, has almost disappeared. It is always due to obstruction. The gross variety which began immediately and continued till death or second operation has disappeared in modern practice. If it occurs now it is from the seventh to the tenth day, the obstruction being the result of the contraction of adhesions, due in most instances, I think, to organisation of blood-clot, causing change in and around the opening in the transverse mesocolon and is always mechanical. It needs one's ingenuity to circumvent the fat or contracted mesocolon and care to control all points of oozing, but I mentioned this in the earlier part of my lecture. But even this is now uncommon, and if it occurs usually yields readily to lavage. The minor cases of occasional bilious vomiting are the result of slight obstruction from rotation of the jejunum.

There are rare and late causes of intestinal obstruction that have been published from time to time, the commonest being that in which the jejunum passes from right to left behind the gastro-jejunostomy, the first published by Barker [53] in 1904 occurred two years after the operation. It is well seen in the drawings of the last case published [54] (Fig. 12) and in another by Bryan.[55] They all seem similar in that practically the whole of the small intestine passes through. It is a complication unlikely to occur after the posterior vertical operation; in both the anastomosis was horizontal. Herniæ through the opening in the transverse mesocolon occurred until this was obliterated by suture. This was recognised as early as 1902 by Moynihan. Retrograde intussusception has been recorded. The late Hamilton Drummond [56] published a case of retrograde intussusception following gastro-jejunostomy and was able to collect and review 13 others. These, however, are all extremely rare conditions and do not detract from the value of the operation.

Late Development of Carcinoma.

(4) We now turn to the possibility of the development of carcinoma in the scar of an ulcer at a time remote from the gastro-jejunostomy. Were this a frequent occurrence it would, of course, be a strong argument for carrying out partial gastrectomy in every case of chronic gastric ulcer. I would say at once that I have never met with this complication following gastro-jejunostomy for a duodenal ulcer, but in one further patient to the one quoted in my Hunterian lecture carcinoma of the stomach developed.

This was a man of 35 upon whom I operated in July, 1916, after a two years' typical history of duodenal ulcer. At operation he had a large ulcer of the anterior surface of the first part of the duodenum. The stomach was normal. He remained well for over three years and served in France. At the end of 1920 he began to lose his appetite and suffered from pain and vomiting. He died in February, 1921, and post-mortem revealed scirrhous carcinoma of the pyloric canal with the thickest and densest part of the carcinoma on the lesser curvature about 2 cm. from pylorus. The duodenal ulcer had healed.

When I reviewed the question in my Hunterian lecture in 1920 I had had three cases in which I had carried out gastro-jejunostomy for chronic gastric ulcer, which died at seven, five, and four years after operation with abdominal malignant disease. All were of the type I now treat by partial gastrectomy. In none was there a post-mortem examination. Since that date no case has occurred, so that I must conclude it is a very rare sequence and one that should not influence us in the treatment of the small free ulcer on the lesser curvature which heals so readily after gastro-jejunostomy.

We must be careful in accepting the presence of a malignant mass in the abdomen after a gastro-jejunostomy as evidence of carcinoma of the stomach or duodenum, or the presence of secondary deposits elsewhere.

I have recently reoperated upon a female patient whose duodenal ulcer I treated by gastro-jejunostomy nearly three years previously. I found carcinoma of the body of the pancreas with secondaries in the liver and spleen. The duodenal ulcer had healed and the anastomosis was perfect. Another unusual case was a male patient of 37, who died of carcinoma of lung one year after gastro-jejunostomy for chronic duodenal ulcer. We were able to obtain a post-mortem and found a thin scar in the duodenum and a perfect gastro-jejunostomy opening. A somewhat similar case was a male of 44, upon whom I carried out partial gastrectomy for a very indurated lesser curve ulcer and a chronic duodenal ulcer. Microscopic examination showed both to be simple. He was readmitted 18 months later with discomfort. He was found to be suffering from carcinoma of his left lung. All three might have been considered as starting in the stomach but for the result of operation in the first, the post-mortem in the second, and the microscopic examination in the third.

I have recently operated upon a case of chronic duodenal ulcer with secondary deposits in the liver from a primary focus in the lung. The case is worth quoting briefly :—

R. M., a male aged 52, was admitted under my care in June, 1925, with a history of almost continuous discomfort after food for nine weeks with vomiting and loss of weight. He was wasted and a definite mass could be felt in the right hypochondrium. His test-meal was 0·28 and 92 and the barium meal showed deformity of duodenal cap. On July 7th I operated, found that the mass I had felt was the liver with a deposit of growth to which the duodenum was adherent. There were several small nodules ; I removed one for examination and then found on separating the duodenum that there was a chronic ulcer with a small perforation. I excised it and carried out posterior gastro-jejunostomy. He lost his symptoms and left hospital four weeks later. Microscopic examination of the duodenal ulcer revealed no evidence of malignancy. The deposit from the liver was carcinoma, and it was suggested that the primary was in the lung. I then had the chest X rayed. The report said, “ Dense shadow in left hilum. Neoplasm almost certainly.”

I have quoted these cases to show that no reliance can be placed on records of carcinoma developing on ulcer after gastro-jejunostomy unless demonstrated at second operation or post-mortem. Moynihan,[57] however, has recorded operating for carcinoma of the stomach 13 years after gastro-jejunostomy for a simple chronic ulcer, the malignant growth being found at its site. This must be a very uncommon occurrence. I can see no reason why carcinoma should develop in a thin scar such as results when a chronic ulcer heals as the result of gastro-jejunostomy, and should look on this solitary case rather as a coincidence. My experience is that carcinoma develops in such a small proportion—certainly less than half of 1 per cent.—of cases treated by gastro-jejunostomy alone that we should not let it influence us, and I am sure I am right in saying that were every case of chronic ulcer to be treated on suspicion as malignant the rise in the immediate death-rate would be far greater than the number of those who might after a lapse of years succumb to carcinoma.

I think it is too often forgotten by physician and patient, and possibly by the surgeon, that gastro-jejunostomy cannot give a new digestive apparatus, but that it can and does, if properly carried out, lead to the healing of the ulcer, prevents its recurrence, and in only a small percentage of cases is it followed by secondary ulceration. But these patients may suffer as other dyspeptics without organic lesions from discomfort after food, and considering this, 90 per cent. of cures without any digestive disturbances is remarkable.

In conclusion, I should like to say as my mature opinion that gastro-jejunostomy is still the most satisfactory treatment for duodenal ulcer and all cases of free gastric ulcer, that its results equal, if they do not excel, those of any other major surgical operation.

EXPERIMENTAL AND CLINICAL INVESTIGATION OF MERCUROCHROME.

BY A. T. TODD, M.B. EDIN., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN, BRISTOL ROYAL INFIRMARY; DEMONSTRATOR OF PATHOLOGY, BRISTOL UNIVERSITY.

THE following account of an investigation of mercurochrome may be of some interest. The preparation is an antiseptic acting powerfully in weak dilution even in the presence of albumins; it penetrates deeply and, although it contains 24 per cent. of mercury, it is feebly toxic. By several local surgeons, particularly Mr. F. Walters, this substance was found to give excellent results in some cases, but in others, apparently identical, its action was disappointing. It was this variability which suggested the investigation. Mercurochrome is stated to be disodium-dibrom-oxy-mercury-fluorescein. It is freely soluble in water, but in distilled water, which has a faint acidity, it is rapidly broken down, especially when exposed to light. In normal saline which is feebly alkaline it is much more stable and appears to keep indefinitely in the dark. A solution in this solvent six months old was recently tested and no alteration was noted. Four samples have been examined, one from the stock of the Bristol Royal Infirmary, and three others obtained by Mr. A. Taylor, the dispenser. For brevity it may be said that no differences in toxicity or antiseptic activity could be determined.

Action of Mercurochrome on Organisms under Varying Conditions.

Its antiseptic power was determined in the following way. Carefully measured amounts, by pipette, of a 1 per cent. solution in normal saline were added to 50 c.cm. of a standard broth; after mixing 5 c.cm. were measured into sterile tubes, giving ten tubes of a constant dilution. To these tubes were added varying amounts of acid, alkali, emulsion of micro-organism, and normal saline. These additions were made with standard Dreyer pipettes. The series was incubated overnight and notes made of increased turbidity, indicating growth in the conditions present, the next day; then subculture of a fixed amount was made to determine survival.

The action of four different samples in solutions aged up to four weeks, dilutions from 1 in 1000 to 1 in 500,000, was tested against nine strains of *B. coli*, one of *S. aureus*, one *B. pyocyaneus*, and three streptococci. The following acids were tested: phosphoric, sulphuric, hydrochloric, nitric, formic, acetic, and lactic; as, however, no appreciable differences were found between them they require no further discussion. On the alkaline side sodium hydroxide was used.

As the full tabulation of these tests would require considerable space, verbal condensation must be substituted.

Effect on S. aureus.—Dilution 1 in 50,000: growth occurred in acidities from neutrality to pH 6·8–6·5. Survival occurred in this dilution to acidity pH 6·0. Dilution 1 in 100,000: growth to pH 6·0; survival to pH 5·0. Dilution 1 in 200,000: growth to pH 5·6; survival to pH 4·7.

It is seen from the above that the actual acidity of the solution is of more importance than the concentration of the antiseptic. At acidities near to the neutral point the antiseptic is so little powerful that the organism can grow in its presence; a relatively slight acidity first inhibits growth and another slight increase causes death.

Effect on B. coli.—Great variability was found. The most resistant strain tested behaved as follows. In a dilution of 1 in 10,000 growth occurred at pH between 7·9 to 5·6. Survival occurred between pH 8·7 to 4·8. The variability of the nine strains is shown by the different acidities at which survival occurred; the dilution was 1 in 30,000. Three strains survived in acidities down to pH 6·8; two strains to pH 6·6; two strains to pH 6·0; one strain to pH 4·6; one strain did not survive at neutrality. One of the strains tested was obtained from a patient who had been treated with mercurochrome for some time; this strain was one of the least resistant found; habituation had not reduced toxicity.

Effect on B. pyocyaneus.—At dilution of 1 in 10,000 no survival was found. At 1 in 20,000 survival was found to pH 6·8. At 1 in 30,000 survival to pH 6·5. At 1 in 50,000 survival to pH 6·0.

Effect on S. equinus.—Dilution 1 in 30,000, survival to pH 6·7; dilution 1 in 50,000, survival to pH 6·0; dilution 1 in 100,000, survival to pH 5·2.

Effect on S. ignavus.—Dilution 1 in 30,000, survival to pH 6·8; dilution 1 in 50,000, survival to pH 6·5; dilution 1 in 100,000, survival to pH 6·0.

Another factor which probably leads to variability in the results obtained with this antiseptic was found when experiments were made to determine whether an increase of the infection would lead to alterations in the results. The amount of infection used in all the above experiments was three drops of an emulsion of a standard opacity. Series of tubes containing equal amounts of a constant dilution of mercurochrome at the same acidity were prepared. To these increasing amounts of the emulsion of living organisms were added and the dilution was kept constant by the addition of saline. The result was of interest; in a dilution of 1 in 2000 there was no survival until nine drops of emulsion had been added; if more than nine drops were added survival constantly occurred. In a dilution of 1 in 2500 at the same acidity and using the same emulsion, it was found that only six drops were needed to ensure survival.

The explanation of this diminution of the antiseptic power of mercurochrome in the presence of a more massive infection is not quite clear. It is known that in a given strain of an organism there are units of different vitality, some weakly, others vigorous; by increasing the number of units the chance of there being one of these vigorous ones would be more likely. If this were the explanation the results would not be so constant, every now and then a vigorous unit would be found in the lesser dilutions. The explanation appears to be the protective action of the increased density, caused by increased amount of bacterial protein added. It was found that with a constant dilution of the antiseptic and a constant acidity the antiseptic action of this substance diminished with increased density of the solvent, especially when the increase of density was due to protein.[1] Thus the solution in distilled water was more toxic than that in normal saline, and that in normal saline greater than that in the standard broth. In normal saline mercurochrome, 1 in 10,000 at pH 6·4, a strain of *B. coli* survived for one hour only; in the standard broth the same strain survived overnight.

Comparison of Mercurochrome and Corrosive Sublimate.

The antiseptic properties of $HgCl_2$ were tested in the same way, and it was found that increasing acidity augmented its power. Weight for weight it was found that $HgCl_2$ was more powerful; thus, in a dilution of 1 in 100,000 in nutrient broth, killing power was increased as the acidity increased, but in this dilution and medium mercurochrome was devoid of killing power on *B. coli.* If a comparison be made relative to the mercury-content, however, it is seen that mercurochrome is the more powerful; in mercury-content 1 in 100,000 $HgCl_2$ corresponds to 1 in 32,000 mercurochrome, which dilution has been shown to be strongly antiseptic at relatively low acidities. Mercurochrome has the advantage that it is not precipitated by albumins, and it will be shown that it is considerably less toxic.

Penetrating Power of Mercurochrome.

The rapidity of penetration of mercurochrome has already been proved.[2] The following experiment emphasises the depth of penetration.

A rabbit of about 2 kilos was anæsthetised with ether and after emptying the bladder a 0·5 solution of mercurochrome was injected under the feeblest pressure possible. The catheter was then clipped and the bladder kept full for one hour, after which the animal was allowed to recover from the anæsthetic. Next day it was killed with chloroform. It was found that the bladder was deeply stained throughout, that the peritoneum round the bladder was deeply stained, and a less deep staining tracked upwards along the attachment of the mesentery. The pelves of the kidneys were distinctly stained, although the pressure of the injection had been far too low to force the ureteric valve.

This explains the finding that intra-ureteric injection is not necessary in pyelitis.

Toxicity for Animals.

The toxicity for animals was found to be less than had been reported; 10 mg. per kilo has been given as a lethal dose.[3] Either the difference is due to the solvent used—i.e., normal saline, with better keeping power—or the rabbits in this country are more tolerant. Altogether 24 rabbits were used, and about 130 injections intravenously or intraperitoneally were made. Old and new solutions of the four samples were used, and no differences could be determined between fresh solutions and those up to three weeks old.

In 1 to 2 per cent. solution there appeared to be no signs of toxicity below a dosage of 5 mg. per kilo. When this amount was exceeded diarrhœa appeared and increased with the dose. At 25 mg. per kilo deaths began; at 35 mg. per kilo rather more than 50 per cent. of the animals died, and the survivors were very ill; 50 mg. per kilo was fatal in about one minute. Excretion appears to be mainly through the colon and the kidneys, and is slow; a rabbit which received 7 mg. per kilo daily for four days was very ill, but recovered. Two female rabbits received 175 and 180 mg. each, spread over ten weeks; they both recovered and between them produced four normal litters, one during the course of the injections.

When death occurs rapidly after a large dose it appears to be due to heart failure; the heart is found to be dilated and is in diastole. In the animals dying after several doses the main changes found were a catarrhal colitis and a varying degree of nephritis. The latter did not appear to be proportional to the amount of mercurochrome injected. The nephritis was mainly tubular and desquamative; but in deaths after large doses, hæmorrhages into the glomeruli and interstitial tissue were found. Pronounced fatty degeneration and calcification, the special features of mercurial nephritis, were not noted.

Mercurochrome as a General Antiseptic.

An attempt was made to determine whether mercurochrome had any value as a general antiseptic. From the in vitro experiments recorded above it appeared unlikely that such would be found. At the acidity of the blood its antiseptic activity was found to be so slight that at the concentrations possible in the living animals such an action appeared to be improbable. Rabbits were inoculated intravenously with virulent strains of *B. aertrycke* and *B. coli*; half were kept as controls, the other half received sublethal doses of mercurochrome intravenously at varying intervals after the inoculation. The result was always the same, the animals which received the mercurochrome died before the controls.

Mercurochrome has frequently been injected intravenously in man, mostly for pyelitis, in which the results are fair. In pyelitis it cannot be termed a general antiseptic ; here it is concentrated in the urine during excretion and, if the concentration and the acidity are adequate, a well-marked local antiseptic action will occur.

Therapeutic Uses of Mercurochrome.

Mercurochrome has been used in many ways and in various conditions ; there is a fairly large literature, mainly in the American medical press. It is hoped that the findings noted above will give improved results. Whatever condition requires its application it is advised that purulent discharges be removed by lavage and that the solution be rendered feebly acid, preferably by means of acetic acid ; the latter should be added drop by drop until the first degree of turbidity appears ; this reduces the pH to about 6·2.

Its chief use appears to be in infections of the urinary tract ; here it is considerably superior to the usual methods of treatment. Subjective symptoms disappear rapidly, but laboratory cure is more slow. The relief which frequently follows a single injection is striking. The method which I have adopted is the following :—

The bladder is emptied, preferably by catheter, and if there is much pus a preliminary wash with normal saline is given. Then 1 to 2 oz. of mercurochrome is introduced and retained for about one hour, after this time it is voided. An injection is given once or twice weekly, depending on the severity of the case. Occasionally some suprapubic pain is noted ; in such a case the mercurochrome can be removed at once, and subsequent injections should be given more diluted. After two weeks to a month the injections may be replaced by sufficient alkali by the mouth to render the urine alkaline. During the time the mercurochrome is being used the urine is kept as strongly acid as possible by means of sodium acid phosphate.

Even in pyelitis the same method is employed ; intra-ureteric injection is not necessary. I have been using this method for out-patients, as well as for cases requiring bed.

In four cases of ulcerative colitis lavage with 6 to 8 oz. of a 0·3 per cent. solution gave good results in three ; the fourth case appeared to have perforated before his admission to hospital. In one of these cases there was much irritability, and a solution in mucilage of tragacanth was more easily retained. As a superficial application it has been instilled or used as a wet dressing and covered with jaconet ; it is very soothing and its penetrating property produces good results. Its injection around septic processes has given some brilliant results ; an account is being prepared.[4] I have only used it in this manner around deep whitlows after incision ; pain was eased and healing appeared to take place more rapidly than in cases not so treated. It may be found of use in pleural empyema and suppurative peritonitis ; in one case of pneumococcal peritonitis I advised its injection, but the patient died. When injected the total amount must not exceed 5 mg. per kilo.

Summary.

1. Mercurochrome is a powerful antiseptic of low toxicity, rapid and deep penetrability, and causes little irritation. It does not precipitate albumins. If protected from light it is stable for long periods in normal saline solution.
2. Its antiseptic properties are augmented by acidity ; they are diminished by increased density of solvent and are likely to be less apparent in heavy infections. Various strains of an organism show differences in susceptibility.
3. At acidities near to normality its antiseptic properties are relatively feeble and it is unlikely to be of value in general infections.

I am indebted to Prof. I. Walker Hall for much advice and laboratory facilities. The expenses of this research have been met by a grant from the Colston Research Fund.

NOVASUROL : A NEW DIURETIC.

By A. R. GILCHRIST, M.B., Ch.B. Edin.

(*From the Department of Therapeutics, Edinburgh University.*)

CERTAIN advanced forms of cardiac failure frequently prove refractory to all therapeutic measures, and this is notably the case when digitalis, dieting, and the common diuretics have no effect in removing the œdema. Therefore, any drug which could be relied upon to invoke a profuse diuresis, relieving the overburdened ventricle, would be assured of a permanent place in therapeutics.

Novasurol was originally introduced by the Bayer Company as an organic compound of mercury for the treatment of syphilis, its composition being sodium - oxymercuric - ortho - chlorphenol oxylacetate with dimethyl malonylurea. Later its diuretic properties were noted by Saxl and Heilig.[1] The drug is put up in sterile ampoules and is administered in doses of 1–2 c.cm. by intramuscular or intravenous injection, each c.cm. containing 0·1 g. of the drug. As a test of its capabilities we have employed the drug in several cases of advanced cardiac failure where the response to digitalis, the diuretics in common use, and the usual therapeutic measures was unsatisfactory—in fact, where the patient's clinical state was virtually at a standstill. As a means of comparing its effects the drug has also been administered to certain other cases. Records of ventricular rate, 24 hours' volume of urine, weight, and vital capacity (V.C.) have been kept throughout treatment—the fluid intake was kept approximately constant. The dose employed was generally 1 c.cm. injected into some œdema-free area, either the buttock or back. Subcutaneous injection must be avoided, as the drug acts as an intense local irritant.

Clinical Records.

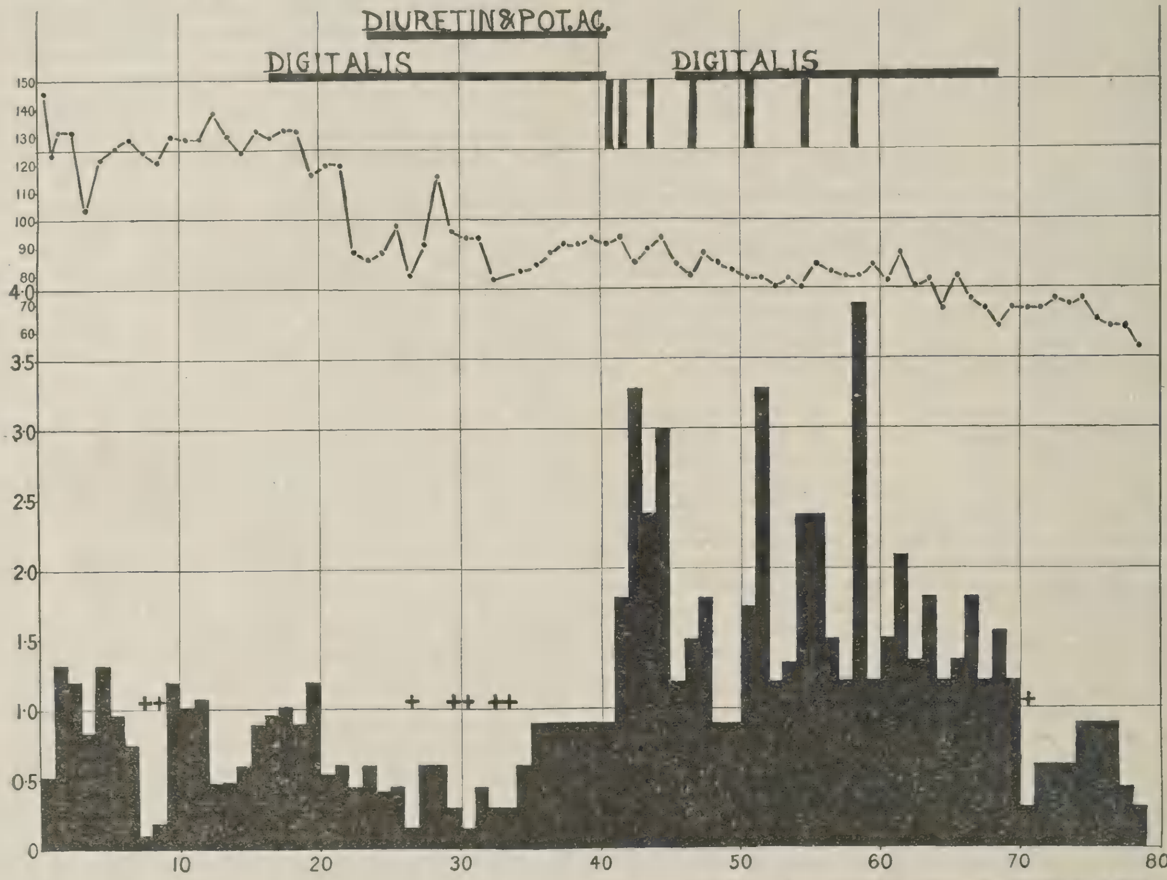
A few clinical examples of its use and effects may be recorded :—

CASE 1.—Mrs. J. A., aged 43, was an in-patient from Feb. 15th to April 23rd, 1924. She was admitted in an advanced stage of failure, which responded well to digitalis and the usual measures. The diagnosis was mitral stenosis with auricular fibrillation. Quinidine restored the normal rhythm which persisted until she was readmitted on May 21st, 1925, with failure more advanced than before, and accompanied by a secondary anæmia. Digitalis slowed the heart without benefit to her general condition, the œdema increased, and the urine output fell to 900 c.cm. Diuretin and pot. acetate were employed without effect. Novasurol was then tried with excellent results. It was necessary to employ the drug on seven occasions, and on the days following its use her urine amounted to 1800, 3300, 3000, 1800, 3300, 2400, and 3900 c.cm. She lost 17¼ lb. in weight. This was accompanied by marked clinical improvement, and she was discharged in good health on August 8th, 1925. This case is shown graphically (see figure).

CASE 2.—J. P., aged 25, suffered from mitral and aortic regurgitation with auricular fibrillation. There was much ascites present, ventricular rate 120, V.C. 55 per cent., and urinary output measured 1000 c.cm. Digitalis produced some improvement (V.C. = 75 per cent.), but a certain amount of ascites persisted. He now received four injections of novasurol at intervals after massive doses of digitalis. His urine measured 2280, 3300, 4080, and 1200 c.cm. The V.C. now rose to 97 per cent. Having lost 17 lb. in weight, he was discharged on April 9th, 1925. He was readmitted with similar symptoms on the 28th, and novasurol was repeated without previous digitalisation, Urine output increased from 750 c.cm. to 2400 and 3300 following two doses, and the heart rate fell from 120 to 66 in 24 hours. The œdema and ascites disappeared. Digitalis was now employed and his condition improved steadily. On discharge his V.C. was 89·4 per cent., weight lost = 14¼ lb., and heart rate = 80.

CASE 3.—A. S., aged 29, suffering from advanced failure due to mitral and aortic disease with auricular fibrillation. Digitalis and diuretin were employed with some benefit, but the œdema and ascites persisted. Novasurol was now employed. The first three doses had little effect, but the fourth, given when fully digitalised, raised his urine output from 960 to 4050 c.cm. on the following day. Steady improvement now set in, his V.C. rising from 32·5 per cent. to 65·5. He lost 54 lb. in weight and was discharged on April 26th, 1925. He was readmitted on July 31st with similar symptoms. The same lines of treatment were carried out, and novasurol provoked diuresis of 2300, 2880, 2320, 1800, 2280, and 2760 c.cm., whereas digitalis alone was relatively ineffective. He was discharged on Oct. 14th, having lost 41 lb. in weight, and with a V.C. of 61·4 per cent.

Case 4.—Mrs. E. N., aged 50, was a patient from Jan. 9th, 1925, until her death on April 24th. She suffered from advanced cardiac failure, secondary to chronic bronchitis and emphysema of 10 years' duration. There was great œdema extending from the feet to the back, and much ascites. Her urine averaged 600 c.cm. for the first ten days in bed. Heart was regular (V.C. = 28·4 per cent.). Digitalis, diuretin, urea, repeated doses of calomel, theocin, and caffeine were all tried without benefit. Novasurol had little or no effect.



Case 1.—Showing urine output in litres per 24 hours (larger figures at left) and ventricular rate per minute (smaller figures at left). The + sign indicates that a portion of the 24 hours' sample of urine was lost on that day. The time during which digitalis, diuretin, and potassium acetate were administered is indicated by the horizontal lines; each injection of novasurol (1·0 c.cm.) is represented by a vertical line. The lower figures indicate days in the ward.

Case 5.—Mrs. M. A., aged 52, gave a history of five attacks of rheumatic fever. The heart rate was 150, regular, and a diagnosis of mitral and tricuspid incompetence was made. There was ascites, and generalised œdema was present, which reached enormous proportions in the legs. Urine output average = 600–900 c.cm., and V.C. was 28 per cent. A massive dose of digitalis slowed the heart, but did not relieve her condition, and urine remained as before. Novasurol induced a diuresis of 2160 c.cm., but improvement was not maintained, and further repeated injections with and without simultaneous administration of digitalis were ineffective. Diuretin, theocin, repeated doses of calomel, Guy's pill, &c., were without avail, and she died on July 14th, 1925.

Commentary.

Of the five cases now reported two failed to respond satisfactorily to the drug. In one, Case 4, diuresis was not produced, and in the other, Case 5, although temporary improvement set in after its use, this was not maintained. Those that responded suffered from auricular fibrillation. In Case 4 the myocardial failure was secondary to long-standing pulmonary trouble, and it is unlikely that any drug could overcome the mechanical causes of the cardiac failure here present. Drugs can only alleviate cardiac failure in so far as the myocardium is able to avail itself of the help offered. In Case 5 the failure to respond to the preliminary diuresis induced by novasurol must be attributed to the fact that the heart muscle was so damaged that its activity bore no relationship to the bodily needs. In both these cases the ventricle was completely exhausted. Further experience will teach how to select those cases which will be able to benefit by the use of the drug, but it is noteworthy that in both unsuccessful cases the vital capacity was reduced to less than 30 per cent. (calculated on West's standards).[2] Peabody's researches[3] have shown the value of vital capacity in following the course of cardiac disease and as a guide to treatment. Both cases also suffered from intense venous engorgement, and in Case 5 the venous blood pressure (Young's method[4]) reached 28 cm. of blood, the normal value being about 10–14 cm. by this method. In Case 1 the results were dramatic; here digitalis and diuretin were of no value, and improvement set in as soon as diuresis lessened the ventricular burden. Cases 2 and 3 also demonstrate conclusively the drug's value, and, as would be expected, the diuresis produced is greater when the patient is fully digitalised. It bears a resemblance to Guy's pill in this respect. The urine output also depends upon the amount of tissue fluids present on which the drug may act.

Novasurol, therefore, appears to be a most suitable adjuvant to digitalis therapy, and is apparently more reliable and more potent than any other diuretic at present in use. Pisani[5] has recorded five cases in which the drug was effective when other remedies, such as theocin, digitalis, and strophanthin, had failed. Oerting[6] had five successful cases out of a total of ten, and in Crawford and McIntosh's series[7] two of eight cases were unsuccessful. Most authorities agree that owing to the presence of mercury in the drug renal disease is a contra-indication to its use. Keith, Barrier, and Whelan[8] have, however, recently reported 12 cases of nephritis successfully treated with ammonium chloride and novasurol. This appears to open up an increased field of usefulness for the drug.

Conclusions.

1. Novasurol is a diuretic of great value in cardiac failure. It appears to be of greater potency and certainty than any of the other diuretics in common use.
2. When employed with digitalis each enhances the other's action.
3. It is suggested that cases which do not respond to the drug have a very low vital capacity, and it is unlikely that any diuretin would be helpful to such hearts.

My thanks are due to Prof. Murray Lyon for placing these cases at my disposal, and for his helpful criticism and advice in connexion with this work.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY.

A MEETING of this Section was held on Nov. 4th, Sir LENTHAL CHEATLE, the President, in the chair.

Dr. J. H. SEQUEIRA opened a discussion on

PRE-CANCEROUS STATES.

He said that the skin aspects of these states deserved more attention than had hitherto been given to them. A pre-cancerous state was hard to define; there were all degrees of susceptibility. Some skin conditions very frequently became cancerous, others but occasionally. The time factor might be the determining one. At any rate, it could be said that there were certain conditions which were potential cancers. For convenience he divided these into congenital and acquired. All conditions of hyperkeratosis, pigmentation, and warty formation were peculiarly liable to malignant change. He illustrated his points by a series of photographs. Xeroderma pigmentosa was a congenital anomaly running in families, a kind of juvenile senility of the skin wherein young children showed all the changes associated with prolonged exposure and might even have definite carcinomata. Occasionally the same condition was seen in the adult. Unna had described a "seaman's skin-cancer" which was the result of any exposure, on sea or on land. The new growths, whether squamous-celled (epithelioma) or basal-celled (rodent ulcer), rarely developed wide malignancy unless they were in the region of the angle of the mouth. To be compared with these conditions was the well-known X ray cancer appearing on the very thin, atrophic, vulnerable, pigmented, and warty skin resulting from repeated short applications or, rarely, from one bad burn. Since the introduction of X ray treatment for lupus the percentage of carcinomata appearing on old lupus sites (formerly 2 per cent.) had greatly increased. Tar and creosote cancers were similar conditions which followed the burning off of the small warts that the workers developed in handling the irritants. The arsenical treatment of psoriasis exposed patients to small doses of the drug over many years and the skin took on an appearance very like congenital keratosis, with a characteristic "raindrop" appearance of the pigmentation. Other forms of chronic irritation that he had found resulting in cancer were the prolonged wearing of a cheap wedding ring and the constant use of a hot poker by a baker. He showed photographs of a case of multiple rodent ulcers on the forearm. The patches had been diagnosed as psoriasis, but histologically they showed a transitional condition of pre-cancerous dermatosis, some of the cells being squamous and some basal. He asked whether surgeons now attached any importance to "dyskeratosis."

The PRESIDENT divided his cases into two classes: the desquamative hyperplasia, which was desquamative only; and the dysgenetic epithelial hyperplasia, which led to tumour formation. Normal epithelial overgrowth, as in the covering of a wound, might be called "genetic epithelial hyperplasia." By "carcinoma" he understood a dysgenetic epithelial hyperplasia associated with invasion of surrounding connective tissue and metastasis. Clearly, such a condition must at first be limited to normal boundaries, and therefore there must be such a thing as a "pre-cancerous state." His definition did not admit the presence of carcinoma unless there were invasion and metastasis; to this there were, of course, a few exceptions, such as rodent ulcer, and there could no doubt be a condition of malignancy or potential malignancy without metastasis. The changes occurring in the breast were, in sequence, a dysgenetic epithelial hyperplasia (sometimes called "chronic mastitis") with a lymphocytosis beneath the skin, warts, papillomata, and then a tremendous hyperplasia of very malignant-looking cells. All these changes were within the limits of the normal, but transplantation of these cells under the skin of another part of the same animal resulted in their growth and malignant metastasis, but transplantation of tar-warts only resulted in atrophy of the transplant or the formation of non-malignant cysts. He thought that these warts were not in themselves malignant, but certainly a source of danger. The lining of the papillomata, however, could certainly become malignant. It was impossible to say in any given case whether or not malignancy was likely to supervene.

Mr. W. SAMPSON HANDLEY said that the essential factor in the pre-cancerous condition was the connective tissue change. Epithelium could not nourish itself properly from the body-fluids; it depended on the connective tissues for nutrition; it might be described as an obligate parasite on connective tissue. It could not grow by itself, but would grow if connective tissue were added to it. Carcinoma began with long-standing inflammatory changes in connective tissue; 20 or 30 years might elapse between the lupus, or the tar irritation and the cancer resulting, which was preceded by a collection of lymphocytes and plasma cells beneath the epithelium. He showed photographs illustrating the permeation of lymphatics and proliferation of the epithelium; a lymphangitis was always present in cancer, lupus, and syphilis. If the ducts were blocked there would be auto-intoxication; possibly this might bear some relation to the "third factor" of Dr. W. E. Gye. In the diagnosis of early breast cancer a valuable sign was deviation of the nipple. If there was deviation in a supposed case of chronic mastitis it should arouse the gravest suspicion.

Mr. ZACHARY COPE regarded pre-cancerous states as essentially a medical condition. He reviewed the examples encountered in the alimentary tract. In the mouth there were three conditions: (1) Leucoplakia; this should be removed if it did not disappear under medical treatment. (2) Papilloma of the tongue, which should always be excised. (3) Dental ulcer; this was always a potential cancer, and should be treated as such if it did not subside rapidly under medical treatment. No pre-cancerous condition could be distinguished in the œsophagus. In the stomach the relationship of gastric carcinoma to gastric ulcer had received much attention with very varying results. Figures had ranged from 75 to 5 per cent., and now there seemed little evidence that a simple ulcer ever ended in carcinoma. Valuable statistics could be obtained if surgeons would investigate the after-histories of perforated ulcers on which they had operated. In the small intestine carcinomata were rare; the papillomata were to be regarded as pre-cancerous, as they were also in the urinary tract. In the large bowel multiple papillomata were certainly pre-cancerous, but there seemed no connexion between cancer and such forms of ulceration as typhoid, except that any form of toxæmia might predispose.

Dr. E. Shaw had no doubt of the existence of a pre-cancerous state. The two main conditions to be considered under the term were chronic inflammations and simple new growths. In chronic inflammation of the breast the changes were many and varied; the epithelium of the acini underwent various alterations of form and arrangement, and might proliferate and project into the cystic acini, but were always surrounded and attached to a thin fibrous basement membrane in simple conditions; if there were clumps of epithelial cells lying loosely in the cavities carcinoma had set in. In his opinion a breast affected with chronic inflammation was in a pre-cancerous state, as also were many skin and mucous papillomata showing invasion of the deeper tissues by superficial cells. In the cervix evidence of development of carcinoma on chronic inflammation was provided by the transition from squamous to columnar and the appearance of definitely malignant groups of squamous cells deep in the muscle. Leukoplakia provided another example. He pleaded for a more intensive study of the morbid anatomy of cancer.

Dr. R. M. Livingstone described attempts to find some difference between true pre-cancerous conditions and similar appearances that were not pre-cancerous. A chemical contrast between acute and chronic inflammation had been determined. The reaction of the tissues in chronic inflammations was invariably acid, while in acute inflammations it was alkaline. Pyogenic micro-organisms at work produced acid which was oxidised by the action of the tissues in acute conditions. It might be that this acid secretion rendered tissues more vulnerable to cancer. Dr. Gye's work bore out this hypothesis. The chemical conditions of the medium which Dr. Gye had found favourable to growth corresponded with the conditions which occur in chronically inflamed tissues. In the alimentary canal fermentation and putrefaction produced similar substances to the putrefiable sugars used by Dr. Gye for culture.

Mr. J. E. Adams described a case of chronic mastitis for which the breast had been removed five years previously; the patient recently returned with cancer in the other breast. Chronic mastitis had been regarded as a pre-cancerous condition, but he and Mr. Halliwell had followed up 135 cases of chronic mastitis where the breast had been removed, and in only four or five cases had cancer developed. It was very hard to find any clinical connexion between the pre-cancerous conditions and carcinoma. Obviously any condition that upset the cellular balance might be regarded as pre-cancerous.

Mr. Lockhart-Mummery said that the commonest precursor of cancer in the large bowel was the simple adenoma, which constituted 80 to 90 per cent. of all the growths met with there. It was possible, however, that other growths might result in carcinoma. It was possible to have two or three carcinomata in the same intestine at the same time, not necessarily as a result of grafting. He had known two cases of carcinoma supervening on diverticulitis, but both were peculiar in that they had perforated.

Mr. D. C. L. Fitzwilliams said that the process of cancer formation in the breast was that for some unknown reason the epithelium became active; when it had transgressed the normal limits of proliferation it might be called pre-cancerous. If it disappeared altogether the result was a cyst and no cancer; if it remained the condition was suspicious. If the ducts were dilated the cancerous cells would escape into the tissues. If a wart appeared it would become carcinomatous in about 12 months. When the basement membrane had been penetrated cancer appeared. The undoubted influence of long chronic irritations seemed to indicate that direct bacterial action was not the cause of cancer. There had been practically no advance made in this subject since Boerhaave first suggested that cancer was the result of chronic irritation.

Dr. E. Haydon asked whether tuberculosis disposed to cancer, quoting cases from his practice in Devonshire, where there seemed to be a special hereditary disposition to cancer, as cases were very frequent.

Dr. Carnegie Dickson said that the pathologist was faced with the most difficult task of setting the margin of malignancy. Many simple tumours could become malignant. In 90 per cent. of cases of chronic hypertrophic endometritis, for instance, the epithelial cells were passing the basement membrane, but not all of them were definitely malignant. He thought frozen sections in the operating theatre were liable to mislead, as a tumour might vary so much in appearance in different parts. It was easy to think there was malignancy when it was not present; metastasis was not necessary for the diagnosis. He regarded myeloma as malignant, although it was often classed among the simple tumours; it certainly had local malignancy. He also regarded rodent ulcer as malignant.

The President, in replying, said that Mr. Fitzwilliams went much too far in saying that cancer was not due to bacteria. Recent experiments had shown that mice could be rendered immune by injection of the ultra-microscopic virus.

Dr. W. Newcomb demonstrated illustrative slides, with particular reference to gastric ulcer and carcinoma. A proof of the previous existence of an ulcer was the fusion of the muscularis mucosæ with the triated muscle of the stomach wall.

HUNTERIAN SOCIETY.

A meeting of this Society was held on Nov. 9th, Dr. F. H. Humphris, the President, in the chair, when the Bishop of Kensington opened a discussion on the

Relation of Spiritual Healing to Modern Medicine.

To many people, said Dr. Maud, spiritual healing suggested necromancy and magic—something not quite canny—especially if the practitioner held the office of, for example, a bishop. The term spiritual healing was hard to define. It had become so confused and meant something different to everyone who used it. It would, however, be hard to give a clearer definition than that put forward by the Lambeth conference. They found that healing was divided into three avenues: the material, which included surgery, the use of drugs and diet, &c.; the psychic, which included analysis, suggestion, and hypnotism; and the devotional, which included prayer, the Sacraments, and reliance on God. Spiritual healing could not be confined to the devotional avenue. All healing was spiritual, and the only unspiritual healing was that which is performed without God. From this point of view he considered the work of the Hunterian Society as emphatically spiritual. Anyone who put his soul into touch with God was by that act alone exercising spiritual power. Unfortunately many people had tended to interpret the term "spiritual healing" as a method directly opposed to physical medicine. It was as unscientific to exclude the physical side as to exclude the mental, for man is composed of body, mind, and spirit. The proper use of faith healing was to use a man's belief in God to reinforce the powers of his body and mind and make him every whit whole. Healing was not simply the removal of physical ailments nor even of faults of character, but the harmonising of a man's whole personality; this was the real health and this was what was meant by holiness. It was disastrous to regard a man as healthy because he had a sound body; to omit the spirit was to omit the decisive factor. The object of the Church was to bring about coöperation between all the means whereby a man could achieve holiness. Methods could not be kept in water-tight compartments. Many people thought that spiritual healing was a matter of faith or suggestion, a department entirely by itself. It was the Church's duty to use all the methods and means given to us and to spiritualise what might so easily become materialised. Much harm was done by the popular feeling that to send for a man's spiritual adviser was an immediate preliminary to sending for the undertaker, and for this reason doctors often deprecated the advent of the parson. It was true that the office for the Visitation of the Sick dated back many hundreds of years and reflected the mind of that period—to a large extent still the mind of to-day—that all illness was the will of God and should be accepted meekly. This attitude contrasted strongly with that of the doctor, whose job was to fight disease to a finish and conquer it. The Church's business was the same, and ought always to have been so. The attitude of Christ was that any form of ill was essentially contrary to the will of God. God's will was health: "I am come that they might have life . . . more abundantly." It was because the Church had not upheld the Christian doctrine in this respect that it had put itself out of court. There was at the present time every reason to hope that the misconceptions which had separated the two professions could be cleared away, and that the help which the Church ought to be able to give in this matter was just what the medical profession would welcome. If we could change people's minds, external things would soon change too. The process was not one of auto-suggestion, depending on one limited personality, but a linking-up with the mind of God. Prayer for the sick was not simply petition. It was getting up to the mind of God and letting the minds of the congregation reflect the thought of the mind of God for the sufferer.

Dr. F. G. **Crookshank** said there seemed to be an urgent need for definition of terms, but that the patron of the Hunterian Society had said that of all things definitions were most to be condemned. We all knew what we meant by the relation between spiritual healing and modern medicine, but we seldom knew what other people meant by it. We needed to think about it, but unfortunately again the great Hunter had exclaimed, "Don't think; try!" The medical profession had been trying hard for many years not to think, with a very fair measure of success. In a way they were right; thinking might lead to a loss of that self-confidence which was so essential a factor in gaining the confidence of others. The general attitude of the medical profession to spiritual healing was something like: "Oh, well, it's all a matter of suggestion, if it's true at all, and any case that was cured by anybody but a doctor must either have been a functional disease or else it wasn't cured, one or the other. Of course, a functional case isn't worth bothering about unless it's rich, and then you consider what operation you might do, or else give it some bromide. As for all this curing by prayer, it ought to be stopped, and it will be when we get a decent authority at the Ministry of Health who will do what the B.M.A. tells him to." Which attitude was very satisfactory to those who held it, but if we wanted to advance the matter we must be very careful not to mistake words for ideas and interpretations for facts. What we took for observed facts were too commonly interpretations. Medical prejudices were never more dangerous than when they dwelt in the minds of doctors who said they had no prejudices. So long as doctors derived their working principles from the dreary agnosticism of the last century, which said that although the physical could and did determine the psychical, the psychical could never affect the physical, so long must there be an unbridgeable gulf between them and the theologians. So long as we believed that mind is a function of matter, so long should we deny that spiritual treatment could affect the physical condition and maintain that spiritual cures were either fancy cures of real disease or real cures of fancied disease. But the psycho-analysts had shown that states of mind must be held responsible for many organic conditions, and it was not good enough to dismiss spiritual healing as phantasy, suggestion, or emotion. Some thought this disposed of the problem, but actually it only made it more difficult. The Huxley-Spencer metaphysics had resulted in a neglect of functional disease by the medical profession; it was a curious thing that this should have been remedied and liaison made possible by the psycho-analytic school, so hated by the theologians. What was hindering reconciliation was that the theologians did not adopt any clear metaphysical creed. It would be helpful if the Protestant churches would define what they postulated as the relation between mind and matter. For his part Dr. Crookshank recognised the truth of the old French physician, "Le médecin fait ce qu'il peut, mais le Dieu seul connait l'humanité." There was no reason why the cure of organic disease, however defined, should not follow prayer and spiritual healing, however defined. There was need to clear away the bogy of distinction between functional and organic disease and between physical and psychical therapeutics. Objectively they were indistinguishable. In the most functional disorders of all there was room for organic changes not yet visible to us. Organic disease might be defined as what we say we can cure and functional disease as what the quacks cure and we wish we could. The surgeons said that the physician's nasty drugs acted by suggestion; why should not the physician say that the surgeon's sanguinary operations acted in the same way? Prejudice and verbal lumber should be set aside to make clear what really does happen. The medical profession had no right to regard the business of healing as their prerogative; their function was to rationalise the business of healing for the benefit of the community. All creatures had the power of reparation, from an amœba to an archbishop, and we called that power the *vis medicatrix naturæ*. A belief in miracles was essential to the doctor's art. The miracle of healing represented the manifestation in ourselves and for others of that power possessed by all creatures for themselves. Why should not some people possess this power in an excessive degree and be able to bring it into consciousness? Were there not human beings who possessed power to heal others in a way that could not be rationalised? The power was exceptional, of course, and comparable with the musical genius of an untaught child. Why did the dog and cat seek a special grass when they were unwell? Cases of spiritual healing might be divided into two groups. In the first there was direct relationship with an objective personality, enriched with more or less ritual and appeal. Successes obtained were unsubstantial unless there was a simplicity of character and strength of personality behind the ritual. The instrument was usually one who had undergone the mystic experience, which was more common than was believed by those who had not had it. Healing was only obtained when the natural powers were released, whether this were in the Harley-street consulting-room or the revival tent. Quite essential was a certain sense of need and helplessness and dependency on a higher power. Dictation of treatment was a bar to conversion or cure. In the second group were those healed by such means as prayer, shrines, waters, &c.; these were mostly functional cases. Spiritual healing was a function of the religious experience in one form or another; there was no justification for holding it to be the monopoly of one creed or one form of practice. It was a curious and interesting fact that although neuroses were very common among Jews, yet faith-healing made no appeal to them, and even the Jewish exponents of psycho-analysis based their theories on purely material grounds. On the other hand, the standard of health was nowhere so high as among the Quakers, who were mystics, and the Plymouth Brethren, who believed profoundly in spiritual healing. The scope of psychotherapy was co-terminous with the whole range of disease, though never to the exclusion of physical remedies. Spiritual methods could be used to mobilise or release that innate capacity of reparation possessed by all, but so often restrained by mental rigidity. Dr. Crookshank was astonished that the theologians did not realise more the strength of their position.

The Rev. **HAROLD ANSON** said that it was important for the clergy and doctors to define spiritual healing; it meant the healing of the whole man, body, soul, and spirit, by all those methods which are according to the will of God or sound logic. In the future it would be quite impossible to heal people in departments. He had been trying for many years to act on this doctrine, and his clerical friends seemed to regard him, until recently, as a dangerous lunatic and the doctors as a criminal. In a neighbourhood full of misery resulting from tuberculosis, venereal disease, and alcohol it was highly unsatisfactory to build a big hospital where the symptoms of these conditions were cured and the patients sent back to the same surroundings and the same misunderstandings. The scientific way of healing was to remedy the unsatisfactory spiritual condition which had produced these diseases—the community's ignorance of what life really is. There was a type of spiritual healing which really tried to get at the underlying wrong thought. Even organic cases could be cleared up by inquiring into and treating home difficulties and distresses.

Canon **DOUGLAS** said that he had had no experience of supersession of natural law. Spiritual healing was coöperation with God to remove an evil. He pointed out that prayer was a concentration on need rather than an uttered petition; it was only valid if backed by the whole human purpose. It was not auto-suggestion nor reliance on some outside power. Spiritual healing was the result of man's efforts with God's coöperation. He had known a case of instantaneous healing in his own experience, but did not regard these events as important; the work of the parson was to get people to concentrate their minds.

Dr. M. **LEAHY** said that he saw no reason for any conflict between the clergy and the doctors. The ills to be healed were of three kinds—bodily, mental, and spiritual—and all three could act and react on each other. Modern medicine was concerned with body and mind; it had nothing to do with eternal salvation, but doctors were nevertheless often asked for advice by patients racked by spiritual doubts. These cases were best left to the spiritual adviser unless their doubts were producing mental disorder. Cases of religious mania and melancholia were better in the hands of doctors. There were two lines of treatment, surgical and medical, and the latter was again divisible into physical and mental. Spiritual healing certainly could not cure gross surgical injuries, acute conditions, or infections by bacteria. The spiritual healer cured by appealing to the mind of the patient, by asking the patient to put his trust in God; why should not the mind be given the credit for the cure? Belief in God and the hereafter was undoubtedly good for man, but an appeal in such terms did not always cure. The cure, when it occurred, was mental; why insist on spiritual intervention? Belief was a mental attitude. He illustrated the mental cure by three cases, one of organic nerve lesion, one of functional paralysis, and one of spiritual doubt. The Primate had set up a permanent committee of six psychotherapists and six clergymen to be advisers to the Church about all such questions as spiritual healing, healing missions, moral obsessions, &c., and there was every reason to hope that an extraordinarily useful phase of coöperation lay before us, particularly in asylums, prisons, and infirmaries. Dr. Leahy had been astonished to find how few asylum chaplains or their medical officers considered that helping the patients was part of their work.

Dr. **EDWIN ASH** said that his considerable experience of psycho-therapeutic measures and his observation of spiritual methods had led him to the conclusion that there must be a focusing point of the influences at work, a centre of action of all these healing measures, and that point was the neurone. The weak point in modern psychotherapy was its forgetfulness of the neurone. There must be some point of fusion or reaction between mind and matter. It was the neurone; the nerve cell was like a condenser tuned to respond to the influences of mind. In spiritual healing we had a way of activating the neurone, by some means not yet understood, through the subconscious mind. If it would react to activities at the periphery surely it must be expected to respond to the higher psychic processes. Spiritual healing should not be concerned with medical matters, such as diet, hygiene, or manipulation. Certain kinds of approach, such as prayer, led to a general improvement in the patient's health rather than to specific healing. The cures would be found eventually to be wrought by natural law on natural mechanisms. Ignorant talk of spiritual healing tended to show its relation to medicine in a false light.

Mr. **MORTIMER WOOLF** said that the ideas of spiritual healing and coöperation had grave dangers; it was a form of atavism to the days when patients looked, and were encouraged to look, to hopelessly ineffective methods for salvation. He asked whether these views were going to influence the public to think that their diseases could be cured by spiritual means and to avoid the practical necessities of modern medicine. If the clergy wanted to coöperate with the doctors they ought to have the same knowledge of fundamental biological processes that the latter won by long years of probation and study.

Dr. **LANGDON BROWN**, in proposing a vote of thanks to the Bishop, said that the day of neglect of functional disease was now gone; the modern doctor knew that when a patient said he was ill when he was not ill he must really be very ill indeed. There was much misery abroad in the world just now, but it was due to a severe attack of growing pains. The hope of the human race lay in the third stage of growth—not physical nor mental, but psychological evolution.

ASSURANCE MEDICAL SOCIETY.

A MEETING of this society was held on Nov. 4th at the house of the Medical Society of London, Chandos-street, W., when Dr. G. G. **HOWITT** presided, and Dr. S. **VERE PEARSON** read a paper on the

End-Results of Artificial Pneumothorax.

The method, he said, was by no means a "cure all" for pulmonary tuberculosis, but it was none the less a great advance in treatment. Patients should be given a chance first to recover under ordinary sanatorium régime, and the cases he would quote were only those which had been given that chance and had failed to respond. All of them had been in the third stage of the disease and had had tubercle bacilli in the sputum. Of 67 patients treated with complete artificial pneumothorax at Mundesley Sanatorium between 1910 and 1922, 26 were now well and working, 35 were dead, several were untraceable, and two were ill with pulmonary tuberculosis. Nine further cases had had their treatment started elsewhere, and four of these were well and the others dead. Of 17 cases of partial pneumothorax eight were now dead and four were well. The average length of life of the 48 patients who had died was $2\frac{1}{3}$ years.

Fourteen cases in which pneumothorax was proposed, but was found to be impossible owing to adhesions, might reasonably be compared with the ones treated. Of these 14, 64 per cent. were dead, whereas only 51 per cent. of 77 complete artificial pneumothorax cases had died. Similar encouraging results, obtained with a larger number of patients, could be found in Dr. J. Gravesen's recent work, "The Surgical Treatment of Pulmonary Tuberculosis," and considering all things it was satisfactory that 32 per cent. of pneumothorax patients from Vejlefjord were still able to work 2 to 12 years after discharge, and that 39 per cent. of those from Mundesley were still able to work 3 to 15 years after starting treatment. Such figures compared favourably with those for general treatment. It would hardly be too much to say that in any case of moderately advanced pulmonary tuberculosis which was fairly unilateral the prognosis was best if artificial pneumothorax was undertaken and proved feasible. Re-establishment of full working capacity could hardly be expected during the first few years; rapid complete recovery was most likely to occur in young patients with sound contra-lateral lungs. The pneumothorax ought to be maintained for at least three years—and often as much as five—and the refills had to be done, on the average, every six weeks; but this did not, as was often imagined, mean invalidism for the patient. The average period for refills in his own patients who had made good recoveries was four years and four months.

Discussion.

Dr. L. S. T. **Burrell** said that the treatment was too new for any well-defined conclusions to be drawn. From the assurance point of view any case that had had active pulmonary tuberculosis was a bad case, but probably those in which artificial pneumothorax had been done were the most hopeful. Considerable study of post-mortem findings had convinced him that the lung on the side treated tended to heal, whatever might be the fate of the other. Whilst he was far from suggesting that the treatment was contra-indicated in bilateral phthisis, he thought it hardly fair to condemn a unilateral procedure because it did not cure both sides, and it seemed reasonable to judge its therapeutic success or failure from its effects on cases in which, as far as could be ascertained, only one lung was diseased. In 1922 he had published results of a series of 43 such cases in which T.B. had been present in the sputum, and two or three months' ordinary treatment in bed had failed. Of these 43 he had described 27 as "arrested," and now, three or four years later, he had found that 24 could still be called arrested and only two had died.

Dr. **Batty Shaw** said that the experience of the two previous speakers made their opinions very important. Unfortunately, the insurance companies demanded exact figures; they wanted to know what were the mortality statistics of patients with an artificial pneumothorax compared with those of healthy people of the same age. Till such statistics could be collected a case of pulmonary tuberculosis would have to be regarded as such regardless of whether it had a pneumothorax or not.

Dr. F. G. **Chandler** said that if a proposer for life assurance had had artificial pneumothorax treatment which had been completed and the lung had expanded again, the assessment of the risk would be the same as in any case of arrested tuberculosis and would depend on the extent of the disease, the general condition of the subject, the ability to undertake full work, the functional efficiency of the lungs, the environment, the intelligence, the length of time since the apparent complete arrest and since tubercle bacilli were last found, the presence or absence of physical signs, the family history, and the complete absence of any suspicious symptoms. Whether the arrest had come about by natural means or by artificial pneumothorax made no difference from the life assurance point of view. If the proposer was still undergoing the treatment, the loading must necessarily be heavy, with later reconsideration, for however well the individual might be there were risks. It was well known that men might do manual work or women bear children, but it was necessary to remember the risk of pleurisy which may possibly interfere with the treatment, the risk that when the lung is allowed to re-expand the disease may awaken into a renewed activity, the risk that the treatment may be abandoned, and the remote risk of a spontaneous pneumothorax. It was interesting to note that nothing had been said of artificial pneumothorax as an immediate measure as soon as the diagnosis of pulmonary tuberculosis was made, and he strongly believed that the early case should always be given a chance of responding to ordinary treatment.

Mr. F. **Sheriff** said that pneumothorax provided a new problem in medico-actuarial practice. The question was: Could a life office offer better terms in the cases treated? Unless the life could be considered an average one it would be unwise to accept such a case, except possibly after the lapse of several years if the general condition and other factors were perfectly satisfactory. Probably the best solution was to impose a decreasing debt extending over a period of 10 or 15 years according to circumstances.

Dr. **Basil Price** said that in weighing up the end-results it was desirable to differentiate between those patients in whom the measure was attempted with the idea of arresting the disease and those in whom it was hoped merely to prolong life. In patients of the latter group there were, however, some remarkable recoveries. He illustrated the difference in prognosis in the two types of case by referring to a series of results obtained by Dr. Alexander Snowden. Of 27 cases in which artificial pneumothorax was done to prolong life only ten remained alive after two years, but of eight in which it was done in the hope of arresting the disease all but one survived over the same period.

The **Chairman** said that the information collected was a useful beginning. It was important to know the facts about the treatment because more and more cases would be coming up for assurance.

Dr. **Vere Pearson**, replying, said that Dr. Burrell's statistics suggested that the majority of those patients who survived three or four years after having an artificial pneumothorax would still be alive after another three or four years. The percentage of cases in which pneumothorax had to be abandoned on account of complications was very small indeed.

An Orthopædic Hospital School.—A conference of representatives of local authorities and other organisations concerned has been held at Nottingham to consider the desirability of providing an orthopædic hospital school for the counties of Nottingham, Leicester, and Lincoln. The Duke of Portland has offered a site of 15 or 20 acres, between Nottingham and Mansfield, and the conference has appointed a committee to inquire into the cost of erecting such a school and the extent of the support likely to be given.

Mr. W. B. Cosens and the Dorset County Hospital.—Mr. W. B. Cosens, who has been honorary surgeon to the Dorset County Hospital since 1895, has resigned that post owing to stress of work; but so intimately has he been connected with the progress of the hospital that it is proposed to mark his services by asking him to retain six beds, together with the rights and privileges of a member of the honorary staff. The opening of an operation room by Sir Frederick Treves in 1903 was a result in large measure of the energy of Mr. Cosens, as also was the provision of children's cots, the installation of X ray apparatus, and the improvement of the hospital in many ways. The committee recently acknowledged with gratitude the sum of £1000 which had been raised by Mr. Cosens for a new electric lift. In the closing years of the last century the average number of operations performed during the year at the hospital was less than 40, whilst now the average is 400.

Reviews and Notices of Books.

TUMOURS OF THE SPINAL CORD.

By Charles A. Elsberg, M.D., Professor of Neurological Surgery, Columbia University. London: H. K. Lewis and Co. 1925. With 354 illustrations. Pp. 421. £2 10*s*.

This is a model monograph. Written by a neurological surgeon of experience, and based on the study of 100 spinal tumour cases personally investigated and treated, it redounds to the credit of all who have contributed to the end-result—a handsomely printed and lavishly illustrated volume conveying information of that practical character which alone can serve. Spinal tumours are not rare; most are amenable to operative interference, and the clinical results not infrequently are brilliant. To attain such desirable results diagnostic acumen of a high class is requisite, for the compression syndrome of the spinal cord follows a variety of pathological processes not all of which lend themselves to successful treatment at the hands of the surgeon. The author describes at some length the diagnostic features of spinal tumours considered generally, and also from the local or regional point of view; distinctions are drawn between intra- and extra-medullary growths, and, finally, differential diagnosis from other conditions of spinal column, membranes, and cord is examined. The reader might suppose from all this that diagnosis has been so simplified as to have reached the stage of "certain," but this is in reality not so. What will impress the student, however, is the evidence furnished by Prof. Elsberg that for accurate diagnosis the radiologist and clinical pathologist have an indispensable contribution to make.

Prof. Elsberg does not appear to utilise the scapulohumeral and carpo-metacarpal reflexes in cervical cases, though their localising value is considerable; nor does he seemingly refer to the bulbo-cavernosus reflex, of similar usefulness in cauda equina and conus cases. There are but scanty allusions to clinical disturbances in the sexual mechanisms in the latter type of case, and none, as far as we have seen, to modifications in body temperature in cervical tumours. Deviation of the umbilicus is another localising sign, of great significance when it occurs, that does not appear to have been remarked or used. But if some differential minutiæ are ignored the general rules of the diagnostic game are fully coded and illustrated. The pathological and surgical sides of the question are particularly well treated, as is to be expected. We congratulate Prof. Elsberg on his mastery of his subject and on his splendid clinical results.

SURGERY.

Selected Papers. By F. T. Paul, D.Sc., Ch.M., F.R.C.S., Consulting Surgeon, Liverpool Royal Infirmary. London: Baillière, Tindall and Cox. 1925. Pp. 292. 15*s*.

This is a reprint of a number of contributions to surgery made by Mr. Paul and is published by the surgeons to Liverpool Royal Infirmary to commemorate his seventy-fifth birthday and the fiftieth year of his membership of the Liverpool Medical Institution. Paul's name will ever be associated with the surgery of the large bowel, and it is interesting to read here the position of this branch of surgery just 30 years ago and the problems which confronted surgeons of those days. With great courage Mr. Paul describes how of seven patients in whom colectomy was tried, four died, and how, as a result of this experience, he was led to devise the operation which goes under his name, and which was followed by most happy results. The first use of a glass tube in acute obstruction of the large bowel was described in 1891. The author also did experimental work on gastro-enterostomy and intestinal suture. In 1892 "the operation of gastro-enterostomy was a prolonged process of careful suturing and was extremely fatal. The bone plate method has changed all this." Yet even after this the aperture nearly always closed down in a very short time, and the symptoms of obstructed pylorus returned. Paul devised an experimental method using bone rings, which was more successful. On page 232 he makes an interesting comparison between enlargement of the prostate and involution mastitis, and in another chapter brings forward evidence in support of the view that chronic mastitis leads to carcinoma mammæ. Both these matters still remain undecided and obscure to this day.

It was a happy thought to publish this collection of papers. We have read the book with great pleasure.

Die Chirurgie. Edited by Prof. Dr. M. Kirschner and Prof. Dr. O. Nordmann. Berlin: Urban and Schwarzenberg. 1925. Vol. III. Pp. 228. M.12.

This volume contains accounts of the surgery of the liver and gall-bladder, written by Prof. Heller, of Leipzig, and the surgery of the pancreas, by Prof. Riese, of Berlin. It may be said at once that the high standard set by the two former volumes has been maintained. Both writers treat their subjects systematically and fully. There is a very good account of the anatomy of the gall-ducts with its variations, and, what is very commendable, a section on the physiology and the so-called pathological physiology of the liver. As was to be expected, the section on gall-stones occupies a large number of pages, and in whatever part of the subject the reader is interested, he is sure to find an adequate account. Cholecystectomy from neck to fundus and fundus to neck are both described, and guidance is given as to which method to select, and there are helpful recommendations on when to explore the common duct and when this step can be dispensed with. A warning is issued concerning closure of the abdomen after cholecystectomy. Heller holds that careful selection of cases must be made to avoid trouble after closure without drainage. The account of pancreatic surgery is as good as that of the surgery of the liver, though naturally it possesses a lesser appeal. The book is well printed, and the illustrations are produced with that excellence we are accustomed to find in German publications.

A TEXT-BOOK OF OPERATIVE ORTHOPEDICS.

By A. Steindler, M.D., F.A.C.S., Professor of Orthopedic Surgery, State University of Iowa. London and New York: D. Appleton and Company. 1925. With 83 plates. Pp. 403 + xv. 30*s*.

Dr. Steindler tells us in his preface that he considers that the manipulative and conservative treatment still has and should have "a hold upon the majority of orthopedic conditions," and it is obvious that under the term "Operative Orthopedics" he includes only such proceedings as necessitate the use of the knife, excluding subcutaneous methods. He has, we think, successfully carried out what he himself describes as the very difficult task of selecting the methods which are the most valuable. He may have been a little premature in including sympathetic ramisection and a little behind the times in retaining the almost abandoned proceedings recommended originally by Vanghetti for the kinematisation of amputation stumps. A somewhat remarkable omission is that of the operative treatment of fractures by such methods as those of Lane and Hey Groves. Subcutaneous tenotomy is dismissed by the author with only a brief description of the operation on the tendo Achillis, although he says that the method is still extensively used. We demur strongly to his statement that in "the early—pre-antiseptic—era even the subcutaneous tenotomies constituted a formidable operation which was often followed by suppuration and other accidents." It would be interesting to learn on what evidence this statement is made, and what was the nature of the "other accidents." We should have thought that it is notorious that the Stromeyerian method owed its wide acceptance to the fact that suppuration scarcely ever follows operations performed according to its principles.

This book will be instructive to surgeons who wish for the first time to perform any of the operations described in it, or who may require to refresh their memory as to details. It will also help them to judge of the prospects of improvement or functional cure which the various proceedings offer. There is a chapter on the Principles of After-Treatment which might well have been longer, for in orthopædic surgery it is a commonplace that at the end of the operation the treatment has, in many cases, only just begun. The book is well printed and the reproductions of drawings and photographs are clear, except a few of the latter which might well be replaced by diagrammatic drawings. There is a copious bibliography with an index of authors and an index of subjects. In the former Sir D'Arcy Power appears under the letter D as "D'Arcy Powers" and Mr. Hey Groves under H as "Hay-Groves."

SEX AND BIOLOGY.

The Sexual Life in its Biological Significance. By J. RUTGERS, M.D. Translated by NORMAN HAIRE, Ch.M., M.B. Dresden: R. A. Giesecke. In six parts. 3*s.* each.

THE author of this work, which comprises six parts in all, was an early advocate of birth control in Holland and believes that problems concerning conduct and happiness should be the concern of all and not limited to savants. In this he is in accord with those modern tendencies which would replace sexual ignorance by knowledge. Part 1 treats of the anatomy of the sex organs, but is discursive and unnecessarily complicated; it is not easy to see what benefit is derived by drawing an analogy between the gonads and pathological tumours or inflammatory products, nor to follow the assumption that the substances secreted by a gland are its waste products, and hence the testes and ovaries are not glands. Quite contrary to medical teaching in this country is the statement that vaginal injections are especially important after menstruation, even in young girls. In Part 2, which deals with physiology, the statement is amplified by the warning that if this practice is neglected "everything goes wrong at the first attempts at connexion." In fact, the sound information and advice that the author offers is marred by frequent observations that are not within ordinary experience. In the section on self-control, for example, we read that "if we remain seated too long at a time the abdomen is doubled up, especially if we lean forward; fatal symptoms of congestion and venous stasis may even occur." The context suggests that these results happen in the seminal vesicles. Dr. Rutgers will find wide agreement here regarding the need for sexual enlightenment, but we fear that the result upon the layman of reading this work would not be to bring sexual information into line with other knowledge, but to make of it something further apart. The translation is well done and presents no trace of German idiom.

A MEMOIR OF BUTLER.

Henry Montague Butler, Master of Trinity College, Cambridge, 1886–1918. A Memoir by his Son, J. R. M. BUTLER. London: Longmans, Green and Co. 1925. Pp. 305. 12*s.* 6*d.*

ANY son who sets out to write a memoir of his father must necessarily start at a disadvantage, for it is almost impossible that he should escape bias. Mr. J. R. M. Butler has, however, overcome the difficulty, and though the love and reverence which he felt for his father are obvious throughout the book, yet as a whole the memoir is "true and indifferent." Butler's life is set out mainly from his own letters, sermons, addresses and the like, and from the estimates and opinions of his contemporaries. The account of Butler's career at Harrow (reviewed in THE LANCET, 1920, ii., 1148) was written about five years ago by Mr. Edward Graham, but as an Oxford man Mr. Graham felt that he would be at a disadvantage in writing an account of the Head of a Cambridge College, and the task devolved upon Mr. Butler.

When Henry Montague Butler was called to preside over Harrow School he was only 26. After spending 30 years at Harrow he became Dean of Gloucester, but after 15 months Lord Salisbury offered him the Mastership of Trinity, a post not without justice considered as the highest distinction in the academic world. He accepted, not without many misgivings as to his fitness, for he was beginning his Mastership at a difficult time in the history of the College. A new régime had commenced under the statutes of 1882, only four years before Butler was instituted in December, 1886; he was Master by a Crown nomination and not by that of the Society, many of whom would have preferred a layman, and he followed two such exceptional Masters as Whewell and Thompson. How he overcame all these difficulties, how faithful and honoured a servant he was of the great Society over which he presided, may be found in the records collected by his son. He had one faculty which is a predominant help to anyone who is called to rule: he always tried to see the best side of a man. Apart from his magisterial office he was, says Mr. Butler, "a great humanist; he was not a great savant." Instances of his finished scholarship are scattered through the book, and range from the beautiful "Frater, ave atque vale" (dedicated to the surviving brothers of the son, Gordon Butler, who died at Kantara in 1916) to the delightful odes upon the two dogs, Carlo and Jet, with their Horatian memories, and the amusing English verses written to help novices concerning Greek particles.

THE HARROW SCHOOL REGISTER.

1845–1925. Second Series. Edited by J. H. STAGDON. In two volumes. Vol. I., 1845–1885; Vol. II., 1885–1925. London: Longmans, Green and Co. 15*s.* per vol.

COINCIDENTLY with the biography of the great Harrovian reviewed above there appears a new edition of the Harrow School Register. The last issue, which appeared in 1910, was already unwieldy, and it has been found convenient to divide the book into two volumes. The new edition is naturally swollen by the records of the Great War. They show not only much distinguished service but a toll of over 600 lives. Dr. H. Saunders, Dr. F. Bennett, Dr. D. V. Cow, Dr. W. E. R. Wood, and Dr. A. R. Chavasse are amongst those who have died since the last edition, and in last year alone Harrow lost two of her most distinguished medical sons in John Hammond Morgan, C.V.O., and Sir G. A. Critchett, K.C.V.O. There are rather more than 50 medical practitioners in the Register.

THE HOUSE OF HEALTH.

By Sir JOHN ROBERTSON, C.M.G., O.B.E., M.D., B.Sc. Medical Officer of Health, Birmingham. London: Faber and Gwyer, The Scientific Press. 1925. Pp. 192. 2*s.* 6*d.*

THIS little book represents one of the latest additions to the series of "Modern Health Books," the aim of which is to place the facts of the chief problems of public health within the reach of the citizen of average intelligence. Sir John Robertson has obviously approached his task with pleasure, and has carried it out with skill. He is quite convinced that a house is something more than a mere assembling of bricks and mortar and so he has laid considerable stress on environment. Tracing the types of dwelling from the snow huts of the Laplander and the sampan of the Chinese to the garden suburb houses of the present day, he shows that it is largely education which has led to the demand for better houses. After discussing the very important question of the site, the atmospheric surroundings, and the water-supply, he goes on to deal with town-planning and the construction of the individual house. He shows as much familiarity with domestic needs and problems as with matters of material and building work, and even the difficult question of finance is cleverly tackled. He deals in some detail with the structural arrangements, internal and external, of a house for an artisan's family of average size, and everything, including cupboards, the bath, the oven, and a place for the pram, receives due consideration. This is a thoroughly fascinating little book, which should be read by all those interested in housing and its problems, and these closely touch most members of the community.

JOURNALS.

The Journal of Physiology. Edited by J. N. Langley, Sc.D., L.L.D., F.R.S. Vol. LX., No. 4. September, 1925.—The Coagulation of Blood Plasma when Divested of Corpuscles, by J. W. Pickering and H. G. Reeves. The experiments aimed at determining (1) the rôle in blood coagulation of the formed elements of the blood; (2) the capacity of plasma to clot in the absence of all corpuscles; and (3) the nature of the precipitate obtained by the prolonged cooling of plasma in an ice-chest (i.e., the thrombozyme of Nolf). The authors summarise earlier conclusions and describe their own work on the arterial blood of etherised domestic fowls. They found that pure plasma collected in paraffined tubes and centrifugalised in the cold contained all the material essential for clotting and conclude that blood coagulation can occur without the intervention of either thrombocytes or tissue juices. A slight increase of hydrion concentration tended to catalyse the clotting of bird's plasma, and lowering the surface tension of the plasma increased its tendency to clot, but did not provoke immediate coagulation. The precipitate obtained by cooling pure bird's blood to 0° C had the chemical reactions of the "thrombozyme" of Nolf. It contained phosphorus and accelerated clotting, but did not appear to be an enzyme, since it was not destroyed by heating to 100–120° C. The plasma coagulated after the removal of this precipitate.—Length of Muscle and the Heat and Tension Developed in an Isometric Contraction, by A. V. Hill. Results are described of experiments (1) on the relation between length and heat production, using the double sartorius of the frog and the biceps cruris of the tortoise suspended in a special myothermic chamber; (2) on the relation between length and the ratio of tension developed to heat produced; and (3) on the mechanical efficiency of the muscle regarded as an elastic body. Amongst conclusions on the relation of heat production to length of muscle is that in resting unloaded muscle the same effects are found for all temperatures and for all durations of stimulus. A mechanism is suggested of the Fenn effect (i.e., more energy is liberated by a muscle when it does external work).—Analysis of the Heat Production During a Contraction in which Work is Performed, by W. Hartree. The sartorius of a frog was stimulated for 0·1 second at 0° C., and Fenn's result was confirmed that when a muscle shortens, doing work, and provided that the weight lifted does not bear on the muscle during relaxation, the energy liberated in the form of heat is constant—that is, it is the same as the heat liberated in an isometric contraction, and independent of the load. In such a contraction, therefore, the muscle supplies extra energy equal to the work done. Analysis of the heat production showed that, apart from the liberation of this extra energy as work, there is a considerable increase in the heat liberated during the earlier phases of contraction. This extra heat is compensated by a deficit during relaxation.—On the Mechanism of Insulin, Part I.: The Action of Insulin and of the Salts of Guanidine on the Permeability of the Mammalian Erythrocyte, by J. Secker. Evidence—quantitative, chemical, and microscopic—from experiments on the oxalated blood of sheep, ox, calf, and cat is given in support of the view that the mechanism of insulin is to increase the permeability of the cell membrane. Guanidine increases permeability in the presence of calcium.—The Reduced Sensitivity to Insulin of Rats and Mice Fed on a Carbohydrate-free, Excess-fat Diet, by H. W. Brainbridge. Rats and mice fed on a diet containing protein, salts, and vitamins, from which carbohydrate was omitted, developed a high degree of resistance to insulin. Apparently an increased amount of carbohydrate and complete absence of fat makes the animals still more sensitive to insulin than they would be on a complete diet, but this is not definitely proved. The variations in the sensitivity are not due to deficiencies in vitamin A.—The Combination of CO_2 in the Blood of the Bull Frog (*Rana Catesbiana*), by H. Wastl and A. Seliskar. The blood at 15° C. is less well buffered than that of mammals. The reaction is probably of the same order as in mammals, though it may be slightly more alkaline.—The Spread of Activity in the Tenuissimus Muscle of the Cat and in other Complex Muscles, by E. D. Adrian. The tenuissimus is over 10 cm. long and a few millimeters wide, and is composed of parallel fibres with no intersections and innervated by a twig from the sciatic nerve. The parallel fibres, each about 2 cm. long, are held together by endomysium, and a stimulus to the curarised muscle produces a contraction found to be limited to 1·5 cm. on either side of the stimulated point. Other results of experiments are given.—Effect of the Circulation on the Electrical Resistance of the Skin, by F. Aveling and R. J. S. McDowall. Chloralosed cats were used, as chloralose make sthe vasomotor system of animals appreciably more sensitive than ether. Intravenous injection of adrenalin (1/50 mg.) brought a marked fall in the resistance of the skin of the limbs and the pads of the feet. The fall corresponded with the rise of the blood pressure on injecting the drug, and the return of the skin resistance to its previous height synchronised with the return of the blood pressure. The authors show that in the cat a fall of electrical resistance of the skin is associated with the constriction of vessels and that a rise is associated with a dilatation.—A Method for the Perfusion of the Kidney with De-oxygenated Blood of Known Oxygen Tension, by E. W. H. Cruickshank and D. Orahovats. The method is also applicable to other organs of the body, while the rest of the body is supplied with blood having a normal oxygen content.—The Innervation of Smooth Muscle, Part II.: Frequency of Nerve Impulses Entering and Leaving the Superior Cervical Ganglion, by Harry O. Veach and Jayme R. Pereira. The experiments were made on cats, anæsthetised by urethane and chloroform. The movements of the nictitating membrane were recorded after the pre- and post-ganglionic nerves were isolated. It was found that the frequency of discharge from the cells of the superior cervical sympathetic ganglion of the cat is directly proportional to the frequency of reception from the pre-ganglionic fibres. It is probable that the propagated disturbances in passing through the ganglion are not altered decidedly in frequency.—On Cellular Changes in Intestinal Fat Absorption, by W. Cramer and R. J. Ludford. Experiments described suggest that in the synthesis of fat in the cells of the intestinal epithelium during fat absorption the Golgi apparatus is the cell structure mainly concerned.—A contribution to the journal on the Composition of Alveolar Air at Extreme Heights, by T. Howard Somervell, is referred to in our editorial columns.

New Nurses' Hostel at King's Lynn.—Some years ago the Queen suggested a number of alterations and improvements at the West Norfolk and Lynn Hospital, and she recently opened the Queen Mary Hostel for Nurses, which practically completes the programme. The hostel, which has cost £8500, contains accommodation for 24 nurses.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 14, 1925.

PRE-CANCEROUS STATES.

THE practical prevention of cancer consists at present in the recognition of the pre-cancerous states to which the Section of Surgery of the Royal Society of Medicine devoted their discussion on Nov. 4th. Of recognisable conditions we can roughly distinguish three categories. In the first place the decennial supplements indicate clearly that some occupations have a much higher mortality than others without there being any obvious local condition to account for the association. Any boy who gave intelligent study to the occupational statistics of the Registrar-General would see that he would have much less chance of dying of cancer if he was a clergyman or an agricultural labourer than if he was a barman or a general industrial labourer; he might or might not act accordingly. In the second place, there are certain chains of events—Prof. BLAIR BELL calls attention to their number (see p. 1003)—which have been identified as often culminating in cancer—smoking clay pipes, being splashed with hot paraffins in the shale-distilling industry, persistent irritation by X rays, and a great variety of other circumstances which all fall under the head of long-continued irritation and among which those associated with the products of burnt coal seem to stand out pre-eminently. And thirdly, we have anatomical abnormalities which are recognised as precursors of frankly malignant tumours, such as melanotic warts, chronic mastitis, and indolent ulcers. How much cancer can be prevented by attention to these occupational, ætiological, and pathological indications—categories which with fuller knowledge will no doubt be merged into one—depends on how far people are prepared to go in taking preventive measures. Removal of the breasts, uterus, and rectum in early life would be extravagant. More people are probably prepared to refrain from the alcohol trade and clay pipes, to be circumcised, and to take various other precautionary measures not more troublesome. But average men and women will not likely do much more than attend to the general cleanliness and hygiene of their skin and alimentary canal, keep clear of modes of life of known danger, and consult a medical man more freely for comparatively trivial symptoms and appearances.

But these pre-cancerous states have an interest and importance for the understanding of cancer as well as for preventive medicine, and in spite of the study which has been given to them there is still much to be found out. The question has been propounded whether a cell becomes malignant because it gets anatomically out of place or whether it gets anatomically out of place because it is malignant. Such a dilemma comes easily to the mind in the contemplation of the distortion of the epithelium at the edge of an old ulcer, where certainly the normal arrangement of epidermis and dermis is not maintained and in which occasionally a virulent epithelioma may arise. It is established that normal epithelium experimentally displaced in a somewhat similar way does not become malignant. But this is not really conclusive that misplacement is secondary rather than primary. Recent studies have brought out emphatically the length of time which may elapse between cause and effect in cancer; men and mice both need to have their skin irritated for about a quarter of their lives before there is much prospect of its becoming cancerous, and even if conditions are so arranged that a single application of hot tar is effective a long time elapses between trauma and tumour. It may well be that experimental displacements fail to imitate the extraordinary deliberation with which the preliminary changes are achieved. The fact that misplacements may be found commonly by the histologists where clinical experience shows cancer to be a rare sequel is also not a final proof that the primary change is in the cell which then by acquired vice inserts itself and its progeny where it ought not to be. Such an argument assumes that we know that a cancer always progresses to an obvious and unmistakable denouement once it has begun. As a matter of fact, there is very little real evidence that this is so. No natural "cause" of cancer is effective in 100 per cent. of cases; most of the causes which have been identified actually produce cancer only in a small minority of all the persons who appear to be exposed about equally thereto. From which it is not unreasonable to suppose that the body possesses means of protecting itself and that it often brings them into play successfully at the very outset of the change.

The question of the cause of cancer has generally been put in the form, "Why do some people have cancer?" The alternative, "Why does not everybody have cancer?" is not quite the same thing, for it suggests a point of view which looks to the resistance of the body as well as to the injury which is inflicted on it. This aspect of the matter deserves more attention than it has had. An obvious tumour might well be the resultant of the normal consequences of a long life and the capacity of the tissues to keep one another in order. The experimentalist, working intensively in a favourable field, can break down the resistance of almost every mouse by tarring it enough; Miss M. SLYE'S inbred race of mice cannot resist the trivial traumata of their ordinary lives and nearly all of them die of cancer. Such is a possible way of looking at the facts and it has been followed by those who, in their study of pre-cancerous states, have looked at the connective tissue rather than the epithelium. With the powerful weapon of analysis furnished by Dr. W. E. GYE it should not be long before such speculations can be replaced by conclusions.

A GREAT PHYSIOLOGIST.

THE roots of medicine that reach down into the rather barren strata of the past give support to the tree; but the sap comes from the small rootlets which have recently been put out into unexplored soil. The new arborescence of medical science is a direct result of fresh root expansion, in which physiology is a vital trunk. The work of those "growing points" who first branched off into new ground has given rise to such a mass of offshoots that it is difficult to believe that so many dichotomies have occurred in one or two lifetimes. The tentative rootlet of yesterday becomes a trunk to-day; on ceasing active work it passes into the supporting rather than the nutritive structure of the tree.

The career of the late Prof. J. N. LANGLEY illustrates the importance of a single life in so recent a science as physiology. The beginning of the modern biological school at Cambridge was, practically speaking, the appointment of MICHAEL FOSTER in 1871 as prælector of physiology at Trinity College. LANGLEY was one of FOSTER'S first pupils, was inspired by him to take up scientific work, and in 1903 succeeded him in the University chair of physiology.[1] His most important contributions to knowledge were concerned with the movements of granules in the cells of secreting glands, the detailed elucidation of the architecture and function of the autonomic system, the theoretical significance of the action of adrenalin, and the physiology of nerve endings. His work on the salivary glands, stomach, and pancreas has so completely established itself that even in the most recent editions of the current elementary text-books the migration of zymogen granules towards the lumen of the alveoli is illustrated by the figures which LANGLEY drew nearly half a century ago. The study of these granules brought him by a natural transition to the study of the nerves responsible for glandular activity. His mind, intensely critical of scientific generalisations, resented the then current theory of the action of antagonistic nerves. He held the view that, diverse as were the apparent actions of the chorda tympani and the sympathetic on the salivary glands, there was but one form of secretory nerve, the alleged antagonism being in his opinion due to the stimulation of vasomotor nerves simultaneously with those of secretion. This work on the sympathetic and the chorda tympani, and especially on the action of drugs on them, opened up the whole question of the minute anatomy of the sympathetic system, just as the study of antagonist nerves in the heart had brought GASKELL into the same field. At this distance of time it is not very easy to distinguish the precise contribution of each. Perhaps it may be said that GASKELL laid down the broad lines of function, and LANGLEY laid down the broad lines of structure. The rami, grey and white; the number of fibres in each; where they originated and ended; what were their detailed functions—all these were matters of the most scrupulous research in the hands of LANGLEY and his pupils. They were worked at chiefly by the nicotine and degeneration methods.

LANGLEY'S work on the autonomic system was probably his greatest contribution. Had it not been done by him, it may even be doubted whether it would yet have been done at all—at any rate, so well. His later researches were less individual in conception. Other minds reasoned as truly about receptive substances; other hands might have demonstrated the detailed action of adrenalin; but in the minute geography of each fibre of the sympathetic system LANGLEY'S school was supreme. His genius for technique was exactly suited to the problem. The *Journal of Physiology* (a recent issue of which is reviewed in another column) is a lasting monument to the literary side of his work. For more than 25 years he was in practice its editor, and never was a periodical edited with more personal care. Whole articles, even those whose subject matter could have interested him little, were re-cast and sometimes almost re-written; and though this may have been irksome to the authors it produced a journal unsurpassed in quality in the literature of physiology. But LANGLEY'S work is not to be judged alone by its tangible expression. To his pupils its highest embodiment is the ideal of accuracy which he handed on to them—accuracy in expression, technique, criticism, and generalisation. They would agree in believing that the greatest tribute they can pay to their teacher is to hand on that high ideal of accuracy to a future generation of physiologists.

Annotations.

"Ne quid nimis."

THE TOLL OF CHRONIC NASAL FOCAL SEPSIS.

IN his Semon Lecture at the University of London on Nov. 5th Dr. Patrick Watson-Williams spoke of the necessity of the specialist "thinking imperially" of the influence of local diseases in other domains,—of remembering "overseas" sub-infections. The influence of sepsis in the mouth, teeth, and tonsils is, he considers, already appreciated, and is even allowed to obscure the factor of sinus sepsis, although there is little doubt that septic tonsils and adenoids are often only sub-infections from primary foci in a nasal sinus. There are two ways in which such a focus can affect the remainder of the body. The infective organisms may be inhaled or swallowed, or the toxins (sometimes even the organisms themselves) may be absorbed into lymphatic or blood circulation. Before passing on to the second group Dr. Watson-Williams mentioned the frequency of sinusitis in children. It is still necessary to determine how great a percentage of cases of so-called pulmonary tuberculosis in which no tubercle bacilli are found are in reality due to sub-infective pulmonary sepsis. The wasting of chronic sinus sepsis with bronchial sub-infection, nocturnal rise of temperature, night sweats, expectoration, and febrile reaction to exercise, affords a clinical picture hardly distinguishable from true pulmonary tuberculosis and often enhanced by a chronic septic laryngitis. Dr. Watson-Williams regards the extraordinarily high percentage of patients with chronic sinus infections who have undergone appendicectomy or have suffered from gastric or duodenal ulcer as most striking and suggestive, and lays great stress on the rôle of the carrier without obvious signs or symptoms, whose constant throat or nose infection is a menace to those around him. In his lecture he quoted instances of families in which a parent had such an infection, and he attributed the subsequent nasal troubles and large amount of appendicitis amongst the children to this cause. Migraine, supra-orbital and occipital headache are frequently due to nasal sinusitis, and intense neuralgic pain of the fifth nerve, of the tic-douleureux type, may be due to a toxæmic neuritis from para-nasal sepsis. The effects of sinus infection in orbital conditions, in rheumatism, and in neurasthenia are well known. Dr. Watson-Williams rightly regards sepsis as of great importance in nervous and mental disorder, and remarks that in the young delinquent it is very frequently responsible for the acts attributed to Satan. In the past too much has been laid at the door of obstruction caused by adenoids, whereas nowadays it is realised that the degree of sepsis and not of hypertrophy is chiefly important. The relationship of the lymphatics of the pituitary membrane crossing the cribriform plate to the peri-meningeal lymph spaces may partly explain the affinity between nasal sepsis and mind and character; but whatever the extent to which this affinity is particular rather than general, it is very real, and there have been many very striking cases in which melancholia, neurasthenia, and mania had been cured by nasal treatment. Though it may be difficult at present, and perhaps dangerous, to differentiate between those cases in which crime is determined by infections and those in which it is a result of innate moral obliquity, it is necessary, Dr. Watson-Williams holds, to consider how far sepsis should be ranged with other toxic causes of mental and moral degeneration, such as alcohol, morphia, cocaine, or syphilis; thus it may be possible to prevent many social and legal transgressions. Infection may be difficult to detect, and it is a serious error to gauge its intensity by the local inflammatory reaction and outpouring of pus, whose relative absence may even show increased liability to systemic poisoning. The active and real coöperation of the aural, laryngeal, and dental surgeon and the physician is needed; but the amount of slight mental disturbance with alteration in character and power of concentration found in domestic life, and the graver manifestations to be seen in prisons, hospitals, and asylums, make a great deal of trouble worth while. "We have learnt," says Dr. Watson-Williams, "to recover radium from rubbish. Can we afford to maintain in these human dust-heaps numbers of men, women, and children who, if adequately treated, might become useful and happy workers?"

RESEARCH ON MERCURY DERIVATIVES.

AMONG the routine remedies for leprosy mercury has long been employed. Within the last 30 years its use has been revived and hypodermic injections of various salts have at one time and another been recommended. The introduction of mercurochrome and its value in septicæmia have stimulated renewed interest in mercury as a germicidal agent, and results have now been published [1] of its experimental use in leprosy. A routine dosage of 2·5 mg. per kilo of body-weight was most easily tolerated, a standard 1 per cent. solution of mercurochrome 220 in distilled water being used. In larger doses stomatitis and salivation were produced. The authors consider that the treatment should be given once weekly. Forty-four lepers treated in this manner have now been under observation for at least a year. In 20 of these the disease was of the active advanced type; 16 had moderately advanced lesions; in six there was active leprosy of comparatively short duration; whilst in two the disease showed no signs of activity. The results obtained do not warrant any undue optimism, but it is claimed that a very definite improvement became apparent in some of the secondary lesions; ulcerating areas healed up, while trophic ulcers responded less readily. In a few instances the recurrence of febrile reactions was no longer noted, and after the first injections the majority of patients claimed to experience a distinct improvement in their general health. In leprosy complicated, as is commonly the case, by pulmonary tuberculosis, no improvement in either disease appears to take place. In surgical practice mercurochrome is still on its trial. It has been found by Bristol surgeons to give excellent results in some cases while proving disappointing in others, and the discrepancy suggested Dr. A. T. Todd's combined experimental and clinical investigation which appears on another page of this issue. In general terms he found mercurochrome to be a powerful antiseptic of rapid action, low toxicity, good penetrating power, and little tendency to irritate. It has the further advantage of not precipitating albumen and of being stable in saline solution for long periods if protected from light. Dr. Todd found the antiseptic properties of the drug to be greatly augmented by acidity, its potency near the neutral point being feeble. For this reason he is inclined to doubt the value of mercurochrome in general infections.

A report [2] on the bactericidal action of some other mercury compounds has been published by a number of workers at the Wellcome Research Laboratories and the Wellcome Research Bureau. They considered that valuable information might be obtained by starting with a comparatively simple substance, mercurating it and a suitable selection of its derivatives, and determining the bactericidal action of the resulting mercury compounds. They selected benzaldehyde as a starting-point and have done much useful work along the lines they laid down, using *B. coli* cultures for the experiments. To discover the reactions of the drugs in differing conditions aqueous solutions, serum solutions, and fatty acid derivatives were used. The serum and oil vehicles reduced the bactericidal activity considerably except in the case of the chaulmoogric acid salt of a mercury benzaldehyde derivative where the activity was doubled, owing presumably to the inherent bactericidal properties of the acid.

BASAL METABOLISM AND THE THYROID GLAND.

THE estimation of the basal metabolic rate is a modern clinical method that has rapidly established its value. It provides a mathematical expression of a definite biological phenomenon, the energy requirement of the organism under various conditions. It has greatly helped to elucidate our knowledge of the metabolic processes in disease and is a valuable guide to treatment. In particular it affords the most accurate means of determining the activity of the thyroid and in diseases associated with under- or over-activity of this gland it finds its greatest usefulness. Dr. F. S. Hansman, who is now director of the biochemical department of the Royal Prince Alfred Hospital, Sydney, has recorded in the *Medical Journal of Australia* (August 22nd) the results of examining 190 patients with thyroid disease whilst he was working at St. Thomas's Hospital, London. In a review of the present knowledge of basal metabolism he states that the basal metabolic rate gives a useful idea of the economy of the individual's body as a working machine. The female basal metabolic rate is normally about 7 per cent. lower than that of the male, and experiment has suggested that the female is the more efficient machine. There is general agreement, he says, that the increase during pregnancy represents the sum of the metabolism of mother and child, and that there is no variation in the mother, and the majority of investigators have found no change during menstruation, though it may perhaps occur in some women. The thyrotoxic patient is a most inefficient machine and requires nearly twice as many calories to perform the same amount of work as a normal person, and accordingly large diets and rest are needed in patients with exophthalmic goitre. Dr. Hansman quotes the work of Boothby and others at the Mayo Clinic, who found that on a diet averaging 5245 calories over 17 days there were 699 calories a day unaccounted for, after making the most liberal allowances for all energy outputs. The nitrogen metabolism was normal and protein food exerted its ordinary specific dynamic action. The increase in metabolism may reach 100 per cent. above the normal; 15 per cent. to 25 per cent. above normal may be considered mild and above 50 per cent. severe. He considers that the basal metabolic rate will not give a true idea of how ill the patient is, as the nervous phenomena and the degree of thyroid stimulation by no means run parallel. On the other hand, the basal metabolic rate may give the differential diagnosis between hyper- and hypo-thyroidism. H. S. Plummer and W. M. Boothby [1] have shown that administration of iodine removes all the clinical symptoms of exophthalmic goitre, though the metabolic rate remains high. The theory formulated to account for these facts is as follows: Some chemical appears in the body that is capable of over-stimulating the thyroid; the resulting excess of thyroxin leads to increased metabolism which may reach a high figure without causing the patient any symptoms of distress. These cases Plummer calls "compensated hypertrophies." In the next stage compensation fails because the available iodine is insufficient and the thyroxin produced is therefore imperfect and causes nervous symptoms. The administration of iodine to such cases restores them to the compensated group and the symptoms disappear. Adenomata of the thyroid affect the production of thyroxin in different ways. The tumour may itself produce the hormone or may stimulate the gland to increased production. In other cases the adenoma seems to depress the thyroid activity, while in about 35 per cent. it has no effect. The basal metabolic rate may help the surgeon to determine whether, and how extensively, he shall remove the growth. Removal usually brings the metabolic rate back to normal if there has been aberration due to its presence. Too liberal removal of gland substance with the tumour causes hypothyroidism. Regular estimation of the basal metabolic rate after operation would often enable the doctor to give thyroid medication before serious symptoms of hypothyroidism appeared. The diagnosis of hypothyroidism may be almost impossible from symptoms alone, and many cases of indeterminate "unfitness" would be cleared up by a basal metabolic rate investigation, which would also be a valuable guide to dosage. It is also an unbiased proof of the value of treatment. Valuable statistics could be obtained if all the patients in a hospital were to have routine estimations of metabolism and the various lines of treatment were compared. The interaction of thyroid and pituitary make basal metabolic rate estimations of value in hypophyseal conditions. In acromegaly the rate may be increased or decreased, and when it has become subnormal organotherapy may be very useful. In long-standing cases of Fröhlich's syndrome the rate may be much lowered. Clinicians know that large quantities of pituitary are tolerated if they can be combined with thyroid, and the thyroid itself stimulates pituitary function, but a watch must be kept on the metabolism if the thyroid is to be given without danger of harm.

RESPIRATORY PHYSIOLOGY ON EVEREST.

A contribution by Mr. Howard Somervell to the September number of the *Journal of Physiology* describes the results of alveolar air analysis during the 1924 attempt to climb Mount Everest. Alveolar air was collected in football bladders from several members of the party at three different heights above sea level, and the samples were taken down to the base camps and analysed. The altitudes were 14,300 ft., 16,500 ft., and 23,000 ft., and the most remarkable feature of the results was the low respiratory quotient at 23,000 ft., which was due to the small value of CO_2 in the alveolar air. At a great height breathing is so rapid (almost 50 respirations to the minute) that the CO_2 is washed quickly out of the alveoli. It appears that at 23,000 ft. the $(CO_2 \div O_2)$ percentage is smaller by some 3 per cent. than at 14,000 ft. During actual motion upwards the pulse-rate was 160–180 per minute, and sometimes even more. The pulse was regular in rhythm and of good volume, but all who went above 27,000 ft. were found to have dilated hearts which took from one to three weeks to recover. During climbing the respiration-rate was about 50–55 per minute, and when a height of nearly 28,000 ft. was reached 7–10 complete breaths were needed for every single step forward and upward. Breathing quickly and deeply at a great height is very easy owing to the low density of the air. In 1924 none of the party was affected mentally by the altitude, as in 1922; minds were clear and tempers and resolution fairly good even at 28,000 ft.; but the simplest tasks—cooking a meal, fetching snow for melting, or taking a photograph—were found very irksome. At the highest camp (26,700 ft.) appetite was profoundly affected, and it was with difficulty that meat was eaten at all. Chocolate and biscuit were managed as a duty, and only pemmican soup and coffee were taken with any real relish, for in the high dry air liquids were the first need. The three weeks acclimatisation and the extra height seem not to have altered the colour index of the blood and the blood pressure appeared to be unaffected.

LEFT-HANDEDNESS AND LEFT-EYEDNESS.

In his "new interpretation" of left-handedness Mr. Parson sets out on an adventure which has attracted so many investigators previously that his book of 180 pages [1] contains 40 pages of bibliography, which is still incomplete. Briefly stated, his theory is that "eyedness" precedes "handedness." The "master eye" of the popular imagination determines which shall be the dominant hand, and as most people are, for some still unknown reason, right-eyed, right-handedness follows, since on account of our physical configuration we can thus aim more naturally and effectively by bringing the object, the hand, and the macula of that eye into line. The argument is attractive, and by means of a simple apparatus called a manuscope the author was able to support it in examining 608 right-eyed children, only 4 of whom proved to be left-handed. The non-agreement with the formula in one of these exceptions he attributes to a defective right eye. It was found, however, in another case, that it was the left eye that was weak. Still, the relationship at the time of examination seems to be established. It was when of 257 left-eyed children only 32 "confessed" to being left-handed, that the investigation became more complicated. This leaves 225 left-eyed dextrals to be accounted for. "Having found," Mr. Parson writes, "that of the hundreds of children examined, virtually all the right-eyed are at the same time right-handed, we are justified in believing that the natively left-eyed, irrespective of their present manual preference, were originally left-handed." But are we really justified? As there were 257 left-eyed children in a total of 877 examined, it follows that, barring accidents, 29·3 per cent. of the whole must be *natively* left-handed. Bardeleben, in 1914, attacking the problem, apparently on Mendelian principles, had come to the conclusion that the number of left-handers who changed to right-handedness was 26 per cent. of all children. This number corresponds closely with the 225 left-eyed dextrals, who were 25·7 per cent. of the total number of children examined, and so far Mr. Parson's argument finds striking support. But can we be sure that no converted left-handers should be numbered among the right-eyed dextrals? The author's attitude towards his four right-eyed sinistrals (who, he says, *claim* to be left-handed) scarcely suggests that converted left-handers amongst the right-eyed would be welcomed, if found, by the investigator. Lacking information on this, however, we can go no further. To return to the 257 left-eyed subjects, we find that Mr. Parson states that only 32 "confessed" to being left-handed. A moderate proportion of the others certainly admitted one or two left-handed activities, but nothing is said as to left-handed tendencies in a majority of the cases. According to Mr. Parson the odd activities referred to "give a hint as to what more detailed investigation of each case might have developed, had time and circumstances permitted." But the validity of his theory depends entirely upon the result of such a detailed investigation. It is suggested that training in infancy and early childhood has altered the habit of using the preferred left hand. There is no doubt that such an influence is almost invariably exercised, but, as we have pointed out, it is possible that of the 608 right-eyed dextral children many would have used the left hand apart from the same parental influence. Is it even certain that a single left-handed activity is an unfailing sign of a thwarted complete sinistrality? The author goes on to say, "the original bias may in some cases be so slight that in infancy a change might take place without the conscious exertion of any special corrective effort on the part of parents." Here two separate problems are involved: The cause for the original bias, and the origin of the elders' disapproval of a bias to the left side. The former may or may not have a physical basis, but the latter undoubtedly introduces a psychological factor. Why is the child of tender age coerced or coaxed, consciously or unconsciously, into the preferential use of the right hand? What enables it to cling tenaciously to one or more left-handed activities, when for all else it becomes right-handed? Is "eyedness" in any way responsible for the survival of any particular form of activity? It is obviously useless to ask the individual why he developed the habit of using the left hand in the first instance. He started too early for him to remember anything about it. The technique of psycho-analysis, however, may throw some light on the question. Mr. Parson's book certainly carries the problem of left-handedness to a higher plane of inquiry than do many of the previous works on the subject.

ADOLPHE SMITH.

The death of Mr. Adolphe Smith at Fulham on Nov. 9th removes the picturesque figure of an octogenarian who had met life at many points. Of bilingual parentage, Mr. Smith was equally at home on either side of the Channel. He wrote an admirable guide to Hyères as a health resort, he was intimate with the small but influential community at Monaco, he was publicly thanked by the French Government for personal bravery in the streets of Paris at the time of the Commune. His deep interest in the international labour movement took him to every continental centre where standards of work were under discussion, and few can have known more of the actual conditions of life of the people of many countries. It was this background of knowledge and sympathetic outlook which gave special value to Mr. Smith's work as Special Commissioner of The Lancet for 40 years. These commissions were set in motion to inquire into various defects associated with social machinery, understood in its broadest sense, at a time when no official body existed for the purpose. Mr. Smith's reports included one on the spread of disease by means of laundrying, in which he found that table napkins from St. James's-street Club were being dried in a Peckham garret over the bed of a small-pox patient, and another on the contamination of uniforms at the Army Clothing Depôt. This report led to immediate reform. He reported on cholera centres in Europe at the danger-point of 1892–94, preparing maps and statistics which helped the progress of epidemiology; for at that time, while the State could legally spend money on investigating the few cases of cholera occurring in this country, there was no official provision for making inquiry on the continent. He reported on the sanitation of a number of continental and American cities, and his revealing survey of the Chicago stockyards was used by Mr. Upton Sinclair in his famous book, "The Jungle." Mr. Smith's investigation into the way of life of East-end tailors having resulted in the setting up of a special commission of inquiry by the House of Lords, he visited 150 sweating dens in the provinces, of which the final outcome was five large blue-books and the initiation of many changes for the better. Articles on the free feeding of school children which he wrote for us were used as evidence in the House of Commons debates which ended in a measure for provision of meals.

In all these ways Adolphe Smith's work was of lasting value to the community, but outstanding for medicine were his reports on the conditions of contract practice 30 years ago. A general movement against the medical man being dragged into contract practice as if it was a profit-making business came to a head at Cork, where the local profession formed a benefit club to be managed entirely by themselves. Mr. Smith went to Cork and set out in a brief letter to The Lancet the stages of the dispute between medical men and the clubs, the importation of outside medical help, the way in which first the hospitals and then the druggists were drawn into the battle against the demand that bankers, large tradesmen, and well-salaried clerks should be admitted to the medical clubs upon the same terms as poorer clerks, artisans, and labourers, with a miserable yearly fee to cover attendance upon every member of the subscriber's family. From Cork Mr. Smith went on to Portsmouth, where he examined the dockyard benefit societies which admitted infants and juveniles as well as adults at the uniform rate of ½*d.* per head per week; from there, to the medical aid companies at Eastbourne, and so on, over the rural and mining areas, with a divergence to Brussels and a final visit to France, where he discovered no harm being done to the dignity and interests of the medical profession by sick insurance companies. In one of these letters he summed up the position of the club medical officer as the wage-slave of a commercial concern, no longer the guardian of public health, but the promoter of a private business. These articles were issued later as a pamphlet entitled "The Battle of the Clubs," which was widely quoted when the proposals for a National Health Insurance Act first came before Parliament. It is remarkable now to recall with what approval Mr. Smith carried out his difficult task. In person he retained throughout life a certain disarming simplicity of demeanour, and his writing gave the impression of one who observed with candour and who set out his observations without prejudice. Among the host of nameless contributors to our columns none can have had wider influence on broad social conditions than Adolphe Smith.

THE PAINTER AND HIS OCCUPATIONAL RISKS.

Attention has often been directed to the occupation of painting mainly on account of risk of lead poisoning. In this and in other countries committees of inquiry have deliberated and reported. Then came the adoption at Geneva of a recommendation that lead paints should be prohibited internationally for use inside houses. Action to give force to this recommendation has not yet been followed in the different countries concerned. The contention has been advanced that some, at any rate, of the symptoms among painters attributed to lead are, in fact, due to inhaling the fumes of turpentine and other volatile solvents used in paints. There are grounds for accepting that these fumes do cause trouble, but the risk from lead poisoning is hardly thereby minimised. Now further trouble is ascribed to these same solvents by Dr. J. A. Turner, Ohio, U.S.A., whose interest was aroused by the occurrence of skin affections among painters under his care. The trouble consisted in an irritating vesicular eczema on the back of the hands and forearms, which, however, quickly reacted to treatment. He proceeded[1] to investigate the various paint substances and solvents used—namely: turpentine; naphtha; white paint composed of zinc oxide, white lead and solvents; iron filler, a mixture of carbon black, petroleum and turpentine; thinner, consisting of turpentine and naphtha in equal parts; and sealer, composed of drop black with petroleum. Guinea-pigs were used; the skin over an area was shaved, and the materials were applied for varying periods. He found that all the substances used had a depilatory effect, which, however, was soon recovered from when the application ceased. But he found, in addition, that the paint solvents can cause dermatitis, and that turpentine, thinner, and naphtha are the chief delinquents. Hence he considered that painters should be warned against using paint solvents for removing paint, grease, and oils from their hands, and be encouraged to wash in soap and water, and afterwards to rinse the skin thoroughly with clear warm water.

[1] Acute Dermatitis Among Painters, by J. A. Turner, Journal of Industrial Hygiene, 1925, vol. vii., pp. 293–298.

THE SEVENTIETH BIRTHDAY OF A REVIEW.

A NEWSPAPER, like a country, school, or family, is mainly an abstraction of the mind. Analyse it and you will find nothing more than an office with the founder's portrait, a mortal editor, a material printing-press, a row of bound volumes, and a copy of the current issue. These, it is clear, are none of them the newspaper itself. They are only appendages to an abstract personality expressed by a name—a name which symbolises every thought or action ever associated with itself. Like children, newspapers are easily conceived, born with labour, and casually given names; it is only then that the real struggle begins. They have a very high infantile mortality; they need to be kept warm until their circulation is established; they have to be nursed through the disorders of childhood; they must be educated; and they must find a job. To live to a ripe age is in itself something of a triumph, and to have lived worthily deserves unstinted congratulation. Such thoughts are appropriate to the seventieth birthday of the *Saturday Review*, for its age is an index of the service that has been given to it and through it and inspires faith that in the future it will have as real a place in the community as it has had in the past. In a pleasing article on seventieth birthdays Mr. Gerald Gould tells the immortal story of the Frenchman who fell out of a balloon and was heard to murmur to himself in mid-air: "Pourvu que ça continue!" In an even more optimistic spirit we congratulate our contemporary.

THE next session of the General Council of Medical Education and Registration will commence at 2 P.M. on Tuesday, Nov. 24th, when the President, Sir Donald MacAlister, will take the chair and give an address. The Council will continue to sit from day to day until the termination of their business.

THE Proprietors much regret the delay in delivery of last week's issue of THE LANCET.

DONATIONS AND BEQUESTS.—Nearly £2400 have been raised by a bazaar in aid of the Ashton and Hurst Sick Nursing Association.—Mr. D. C. Edwards, for 50 years clerk to the board of guardians, has given £1000 to the Llanelly Hospital.—Miss Elizabeth Ann Vaughan, of Royston, Herts, besides other bequests, left £1000 to St. Dunstan's Hostel.—Mr. and Mrs. Lye, of Rochdale, have given a donation of £1000 to the Royal Albert Institution, Preston.—A legacy of £20,000 was made to University College, Southampton, by Mr. George Moore, of Lordswood, Southampton, once a member of the College council.—Mr. William Fletcher Rogers, Wallasey, Cheshire, besides other bequests, gave £500 each to the Chester Royal Infirmary, the Wallasey Cottage Hospital, the Victoria Central Hospital, Wallasey, the Star and Garter Hospital for Disabled Soldiers, Richmond, Surrey, and the Wolverhampton Royal Orphanage: and £250 each to Dr. Barnardo's Homes and the Agnes Weston Homes for Sailors, Portsmouth. After other bequests he left the residue of his estate for deserving charities in the City of Chester or the County of Cheshire as his two sisters may decide.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CXLVII.—THE TREATMENT OF OBESITY.

THE modern treatment of obesity is based on the subdivision of this condition into two main types, in which the exogenous and endogenous factors respectively play the chief rôle. In the exogenous, the ordinary form, there is an excess of food intake over energy expenditure in an otherwise healthy person, while in the endogenous there is a tendency to accumulate fat independently of these causes. There is usually in the latter condition an alteration of function of one or more of the ductless glands. Naturally, cases occur which must be regarded as transitional forms between the two; these types will be considered under a separate heading.

Exogenous Obesity.

Diet and exercise are the two most important points to attend to in the treatment of this form of obesity. It is possible to reduce weight by diet alone, but exercise is of great value in maintaining the tone of the muscles. It also facilitates the loss of weight by increasing the total metabolism.

Diet.—The bulk of the fat of the tissues is derived from carbohydrate, the remainder from fat. It is usual to cut down the fats to a minimum and allow a certain amount of carbohydrate in the form of vegetables. Bulk can thus be obtained in this way and the appetite satisfied. A low fluid intake is not necessary or desirable, except, perhaps, in cases with cardiac complications. Obesity can be reduced safely on a great variety of diets, so long as sufficient protein and carbohydrate are given to prevent loss of body protein. Of a number of schemes advocated from time to time, the dietetic régimes of Banting, Œrtel, Ebstein, and Von Noorden are probably the best known. In these diets the proportion of protein is increased, while the carbohydrates and fats are reduced to various extents; for details reference must be made to the original monographs. A satisfactory diet should contain a considerable amount of protein in the form of lean meat and fish, a moderate amount of carbohydrate in the form of vegetables, and little fat. Of fish, salmon, herrings, and sardines, containing more than 10 per cent. fat, should be avoided. Poultry, with the exception of duck (30 per cent. fat), may be allowed. Vegetables containing more than 10 per cent. carbohydrate should be used sparingly; the chief of these are the following: Potatoes, 16–20 per cent.; green peas, 13; broad beans, 14; broccoli, 10; onions, 10; parsnips, 18; artichokes, 17. Sugar is better cut down to a minimum and breadstuffs limited to one or two slices a day. All forms of bread contain a large proportion of carbohydrate, varying from 45–65 per cent., and the percentage in toast may be as high as 60. It should thus be condemned. Bread is a difficult article of diet to replace; the quantity must, however, be strictly limited or a patent bread made with casein (prepared for diabetics) may be substituted. Fresh fruit may be allowed in moderation. Bananas, cherries, grapes, and greengages contain more than 10 per cent. carbohydrate and should be restricted. As to cooking, the ideal form is grilling; boiling or roasting may also be employed, but frying should be avoided.

It should rarely be necessary to calculate the caloric value of the food intake. It is important that the body-weight should be controlled by weekly measurements. In most cases it is best to arrange the diet so that the weight is reduced gradually by 1 to 2 lb. a week. This prolongs the period of dieting and accustoms the patient to a small amount of food; he is less likely to overeat again.

Exercise.—The second essential in treating this form of obesity is exercise. Muscular exercise increases the metabolism more than any other factor, and the loss of weight is accelerated. Moderate exercise has been found to increase the metabolism three times, severe exercise as much as nine times its normal rate. Obese patients cannot, of course, take severe exercise without throwing an undue strain upon the heart and circulation, but active exercise can generally be arranged on a graduated scale. When the degree of obesity prevents active exercise the chief substitutes employed are massage, active and passive movement, and faradisation. Massage strengthens the muscles and facilitates the taking of active exercise, but its direct effect on metabolism is slight. Faradisation in the form of the Bergonié system has lately been used considerably; by this means the principal muscles are made to contract rhythmically and in regular order against a load. Most cases of exogenous obesity respond to diet and exercise; the use of thyroid extract is seldom necessary or advisable. Recently, attempts have been made—it is claimed with success—to treat certain of these cases by a combination of subcaloric diet and thyroid extract, but it is probable that these patients really belong to the endogenous group. They are chiefly of the type developing after childbirth and associated with menstrual disorders. The administration of thyroid extract is controlled by repeated estimations of the basal metabolic rate, which is maintained at a level of about +10 per cent. The uncontrolled employment of thyroid extract in obesity is to be condemned.

Endogenous Obesity.

In this form of obesity fat is deposited independently of food intake and energy expenditure; diet and exercise are no more than useful adjuvants to treatment by gland extracts. In endogenous obesity there is a defect of metabolism due to deficient function of certain of the ductless glands, notably the thyroid, the pituitary, and the genital glands. When their function is defective, the ability to metabolise food, and particularly carbohydrate, is subnormal. There may also be a type of endogenous obesity due to excessive secretion of insulin, and the frequency with which obese patients develop diabetes suggests that this supply may ultimately become exhausted; but this condition is not yet definitely recognised.

Differentiation between cases of the exogenous and endogenous groups is not always easy. Onset at or about puberty, or in women after childbirth or at the menopause, and associated disturbances of growth, menstruation, and other conditions suggest a ductless gland disturbance. In other patients endogenous obesity is inherited and appears shortly after birth or about the time of the second dentition. Certain metabolic investigations enable a distinction to be made between these two groups. In the endogenous form the basal metabolism and the tolerance for sugar are usually both abnormal. These tests can be made without difficulty at the bedside. The former is chiefly of value in cases of suspected thyroid deficiency, while the latter can be used to unmask a defective mechanism for dealing with sugar in endogenous cases.

Obesity of Thyroid Origin.

Obesity of thyroid origin must be suspected when a rapidly developing obesity occurs with slight symptoms of hypothyroidism, puffiness of the feet, apathy, diminution of memory, and subjective feelings of cold. The basal metabolism is usually subnormal and should be investigated. Thyroid extract acts as a specific and can be employed as a functional test. The tolerance for these extracts is remarkably high. Withdrawal of food, on the other hand, is tolerated badly. Cure by thyroid extract is rapid and complete. A reliable desiccated extract of the gland should be used and given in gradually increasing doses, starting with gr. $\frac{1}{2}$ once a day and working up to a point at which the patient loses 1 to 2 lb. a week. This rate of loss should be maintained, though as the tolerance increases it may be necessary to increase the dose still further. These patients may require as much as gr. 15 of the desiccated extract a day. The dosage can be more accurately regulated by repeated estimations of the basal metabolism, an attempt being made to maintain it at a level of about +10 per cent. Marked acceleration of the pulse or glycosuria indicates the temporary withdrawal of the extract, or diminution of the dose.

Obesity of Pituitary Origin.

The fat distribution is characteristic, being especially marked around the girdles. The degree of obesity may be excessive and is most commonly found in children and adolescents. It is usually accompanied by disturbances of growth and genital function. When the condition is due to a pituitary tumour little can be expected from treatment by gland extracts, but in other cases there appears to be only a disturbance of function. In these patients the basal metabolism is low—probably due to a secondary thyroid factor—and the carbohydrate tolerance abnormal. The literature contains numerous statements that in such cases pituitary extracts are of value when given by the mouth, the obesity being remarkably relieved in some patients. Thyroid extract is usually said to be of value, though the results are not so uniformly satisfactory as in cases of the true thyroid type. From our experience at St. Thomas's Hospital we have come to the conclusion that pituitary extracts, whole gland, anterior lobe, or posterior lobe are not effective in reducing the obesity of these patients when given by the mouth. They have, however, a definite effect on their carbohydrate metabolism, and when given with thyroid extract greatly enhance the effect of the latter. We conclude that the best results can be obtained by treatment with gradually increasing doses of thyroid extract and whole gland pituitary extract, starting with gr. $\frac{1}{2}$ of each and working up to a point at which the patient loses 1 to 2 lb. a week. Some cases may require as much as gr. 15 of each extract a day. More accurate regulation of the dosage can be obtained by repeated estimations of the sugar tolerance. Reliable desiccated preparations should be used.

Obesity of Genital Origin.

The tendency to obesity, observable in both sexes after castration, is generally attributed to the loss of the secretion of the genital glands. That treatment by extracts of these glands has not up to the present proved effective may be due to lack of effective preparations. The same may be said of the treatment of eunuchoid obesity. It is possible that genital grafts may ultimately prove to be the solution of these problems. Some of these patients can undoubtedly be helped by dietetic measures, others by thyroid extract. As their basal metabolism is sometimes low and carbohydrate mechanism usually defective, the latter is probably the best method of treatment at present available.

Transition Forms.

A number of cases of obesity develop at times when the function of the ductless glands is known to be disturbed; for instance, in women after childbirth or at the menopause, or after some infectious illness. They are not usually regarded as cases of endogenous obesity, but due rather to the sedentary habits and overfeeding of convalescence. In other persons, under exactly similar circumstances, obesity does not result, so that presumably there must be some additional factor. The mechanism of these persons for dealing with sugar corresponds to that of the endogenous type, the curves being nearly always abnormal. Again, treatment by diet and exercise is frequently ineffective in reducing their obesity, while good results can be obtained from treatment with thyroid and whole gland pituitary extracts. It would appear advisable to take all these points into consideration when dealing with any individual case of obesity.

CANCER STATISTICS.

By J. E. Rush, M.D.,
DIRECTOR, DEPARTMENT OF HYGIENE AND PUBLIC HEALTH, UNIVERSITY OF KENTUCKY.

It must be apparent that vital statistics, their collection and interpretation presupposes a dual type of training. Biometrics (of which vital statistics is a part) is simply mathematics applied to a biological problem. The mathematics involved is far the simpler consideration, for in order to have the deductions of any value whatsoever, the student must have a clear-cut conception of all the underlying biological factors which influence the collection of the data with which he is working. Obviously, one is not entitled to use a precision measure indicating that the result is correct to 1 part in 100, if in the collection of one single factor there is a probable error of 10 per cent.

Mathematics applied to a Biological Problem.

The handling of figures as applied to vital statistics is relatively easy from a mathematical standpoint, while from the medical standpoint it is fraught with extreme difficulty. To add, to multiply, or divide, to figure rates per 100,000 is nothing but simple arithmetic. To know the limitations of differential diagnosis, the difficulties in the interpretation of physical signs and laboratory data, to have made out death certificates where you could not be absolutely sure, even of the primary cause of death, are all necessary experiences before one is at liberty to interpret vital statistics. Here, perhaps more than anywhere else, does the maxim "Figures don't lie," &c., find its best application.

How does this apply to cancer? There is a group of statisticians that contend that the incidence of cancer is actually increasing; others say that the increase is only apparent and not real, that it is due to better diagnosis, to better reporting of the causes of death, &c. It is certainly important for us to know the truth because science is dependent upon truths, and, furthermore, such knowledge may influence our methods of attack on the problem.

In order to arrive at a basis for the comparison above indicated, it is obviously best to select census years which are sufficiently separated to show any changes (if, indeed, such changes exist) so that we are not forced to draw conclusions from slight differences in data, from which deductions of the kind to be made are not warranted, simply because the slight differences shown are not significant in view of the precision of the biological data subjected to analysis. For many reasons it is thought that a recent ten-year period could best serve our purpose, and for this reason the years 1910 and 1920 have been selected. The intervening census years have been examined in order to be sure that the years selected were representative and that no particular factor, not usually operating, was met in the two years cited.

In the interpretation of vital statistics based on mortality rather than morbidity many seem to feel that there is a great element of precision which allows the manipulation of such data in a purely mathematical manner, and that deductions stated with great mathematical accuracy are warranted. Whatever may obtain elsewhere, this certainly is not true in cancer. It is not necessary to point out to the physician that neither tumour nor cachexia nor both occurring in the same individual are pathognomonic of cancer. One or both of these conditions are frequently met in the anæmias, in arterio-sclerosis and the like, and until we have a different attitude on the part of the public toward post-mortem examinations, these great factors will always influence our vital statistics, even our mortality reports. We must, too, be very careful of false correlation. Only recently it has been stated that the cancer curve has paralleled the increased use of machinery; but to prove that these bear a cause and effect relationship to each other is quite another matter.

Analysis of Reported Increase.

From 1910 to 1920 there is a reported rate increase in the incidence of cancer from 76·2 to 83·4 per 100,000, or over 9 per cent. (1) What are the important differences in the U.S. registration area of 1910 and 1920? (2) What factors or appliances have entered the field of medicine to help in making a better diagnosis of cancer? (3) To what extent has the saving of lives in the lower age-groups increased cancer as one of the causes of death in the upper age-groups?

Let us analyse the statistics of these three years before we answer (see table).

Cancer (including Sarcoma and Hypernephroma).

—	1910.			1915.			1920.		
	Total deaths.	Per cent. of total.	Rate per 100,000.	Total deaths.	Per cent. of total.	Rate per 100,000.	Total deaths.	Per cent. of total.	Rate per 100,000.
Buccal cavity	1,576	3·8	2·9	2,123	3·9	3·2	2,679	3·7	3·1
Stomach and liver. ..	16,475	40·1	30·6	21,221	38·9	31·5	27,489	37·7	31·4
Peritoneum, intestines, and rectum	5,258	12·8	9·8	7,332	13·4	10·9	9,792	13·4	11·2
Female genital organs..	6,147	15·0	11·4	8,120	14·9	12·1	10,797	14·8	12·3
Breast	3,730	9·1	6·9	5,163	9·5	7·7	6,665	9·1	7·6
Skin	1,459	3·6	2·7	1,955	3·6	2·9	2,367	3·2	2·7
Not specified	6,394	15·6	11·9	8,670	15·9	12·9	13,142	18·0	15·0
Total	41,039	100·00	76·2	54,584	100·00	81·2	72,931	100·0	85·4

The precision of the data is not such as to warrant us in using the number of significant figures shown in the column entitled "Per cent. of total deaths." The mathematics have been extended in order to make more apparent the differences (should any such exist).

The rate per 100,000 has increased from 1910 to 1920. In 1917 and 1918 much comment was provoked by the apparent arresting of the upward trend of the cancer curve and many explanations were advanced to account for it, such as: 1. The educational programme intended to reach the public with the message that early cancer is curable has begun to bear fruit. Subsequent statistics have proved the incorrectness of this theory. 2. Another most interesting theory was that the war-time diet of the country had influenced the cancer-rate. Diet (on the calorie basis) is terribly over-emphasised as a factor in public health problems, and again we must recall that there was really no very great national change in our modes of living (including diet) during the war. While not attempting to answer the question raised by the statistics of 1917 and 1918, we must remember that the flower of the medical profession was abroad or in camps on this side; that, to take their places many graduates who had never before practised medicine and many retired physicians were pressed into service to meet the public needs. I have no doubt that this accounted for the difference in our vital statistics. 3. That the influenza pandemic took its greatest toll in the age-groups in which cancer is not particularly met is, I believe, an established fact. Many have claimed that the decrease of deaths due to 'owered infant mortality, the reduction in typhoid fever, tuberculosis, and the like gives an increased incidence in those diseases of the upper age-groups, of which cancer is one. When we recall that effective work of this kind has only been in operation for 10 or 15 years, it is difficult to imagine that the child hygiene and typhoid fever (a disease usually of adolescence) prevention programmes would have yet brought great numbers of individuals into the age-groups where cancer takes it greatest toll.

Perhaps there is some reason to consider tuberculosis alone—this disease has caused (and is causing) so great a mortality—too, we must recall here that the effective work in preventing tuberculosis has apparently decreased the mortality from this dread disease nearly 50 per cent. This is a factor worthy of some consideration, but it may be stated here that the average (and it is very dangerous to deal with averages) age of death as computed from the 1920 mortality statistics is about 35 for tuberculosis, while the same for cancer is over 55 years.

Let us examine the tables above given for cancer mortality in the years 1910, 1915, and 1920. We note that there has been a great increase in the total deaths from cancer and also in the deaths from cancer in the various locations of the body. Undoubtedly most, if not all, of this increase is due to the addition of Minnesota, Montana, and Utah (1910), Kentucky and Missouri (1911), Virginia (1913), Kansas (1914), North Carolina and South Carolina (1916), Tennessee (1917), Illinois, Louisiana, and Oregon (1918), Delaware, Florida, and Wisconsin (1919), and Nebraska (1920), to the registration area of the U.S. as it existed in 1910. The group recorded as "not specified" amounts to from 15 to 18 per cent., unfortunately. This must be interpreted as representing a probable error in the statistics of cancer as reported by location of nearly this magnitude.

There is no one who would claim that our ability to diagnose cancer of the buccal cavity, breast, or skin (which caused the death of the patient) was much better in 1920 than in 1910, but it might be thought that the development of the X ray (particularly if it had been more widely used) might have shown an increased incidence in cancer of the stomach, peritoneum, intestines, &c. No such increase is apparent from an examination of the distribution of cancer in various anatomical locations in 1910, 1915, and 1920. Besides the increase in the total deaths from cancer in the various years shown, there is also quite a definite increase in the rate per 100,000. However, quite a percentage of this increase is found under the head of "not specified," which is, without question, the least reliable of any of the figures above given.

Conclusions.

Some of the statements made above are further strengthened by a report entitled "Mortality from Cancer," &c., prepared in 1914 by the U.S. Bureau of Census, which is a special study of the incidence of the disease. This is the most careful statistical study of cancer in the U.S. which has ever been made. The following facts are gleaned from the report cited. About 2000 death certificates from an estimated 50,000 deaths from cancer were examined, and it was found that in only 2 per cent. of the cases was the diagnosis confirmed by autopsy and in only another 9 per cent. had an operation confirmed the clinical diagnosis.

On the basis of the returns for 1913 it was assumed that about 8500 deaths would be reported as due to cancer of buccal cavity, skin, and breast, "all so situated that no mistake would be probable in diagnosis, and that these, therefore, could be classified as of reasonably certain malignancy." This would mean that in 14,000 cases the diagnosis was "reasonably certain," leaving 36,000 cases in which it was proposed to write to physicians for additional information. About 35,000 letters were sent to physicians and replies received in about 80 per cent. of the cases, with the result that the Bureau was able to compile 30,555 deaths, or 58·3 per cent. of the total appeared under the caption of "Diagnosis reasonably certain," 27·5 per cent. under "Diagnosis uncertain," and 14·2 per cent. under "Diagnosis unknown." With this lack of accurate and definite information in the best cancer study that has ever been undertaken in the United States, are we justified in assuming that a recorded increased change in the death-rate from 76·2 per 100,000 in 1910 to 83·4 in 1920 is indicative of an increased incidence in cancer? With a definite admitted lack of precision of 14·2 per cent. and a possible error of 41·7 per cent. in the collection of the statistics, are we justified in attaching any importance to a change in the end-result of the magnitude of less than 10 per cent.?

Obviously we have not statistics of sufficient accuracy at hand to be certain that cancer is increasing, and the burden of the proof that it is must rest with those who claim that such is the case.

MATERNAL MORTALITY.

A CONFERENCE arranged by the Post-Certificate School was held at the house of the Royal Society of Arts on Nov. 9th to discuss

How the Midwife can Help to Reduce Maternal and Infantile Mortality.

Dr. J. S. Fairbairn, who opened the discussion emphasised the importance of making the services of the doctor and of the midwife complementary and not rival. In his opinion the normal labour should be conducted throughout by the midwife; the practitioner should supervise the pregnancy, give antenatal care and instruction, and be ready to deal with any abnormality beyond the scope of the midwife's training. The Scottish Board of Health had remarked in a recent report that the doctor was too expensive and highly trained an instrument to use for normal labour. If this was to become the rule it was most important to get the best possible people into the midwifery service. There were not nearly enough fully trained nurses practising midwifery, and it was essential in the interests of public health to devise some means whereby the best class would be attracted. He thought that the practice of midwifery should be made a stepping-stone to public health appointments and the conditions of the midwife made less burdensome. This was the day of team work, and team work between midwives and general practitioners would add greatly to the public health services of both.

Miss Doubleday drew attention to two outstanding statistical facts; that since the passing of the Midwives Act there had been practically no change either in the maternal mortality-rate or in the infant mortality during the first month after birth. She pointed out that 50 per cent. of the births in this country are attended solely by midwives. The reduction of these mortality figures was largely a problem of housing, and she questioned whether the provision of more hospital accommodation were the best solution for normal cases. The routine of the well-equipped hospital did not help the woman when she returned to her own conditions. The midwife in attendance at the home could educate her and show her how to make the best use of those conditions. A very important factor in this education was the father, who was entirely neglected under the hospital system. Educational authorities had been inclined in the past to leave the father in the dark and had not attempted to teach him that his help was really needed. The midwife's work was essentially to advise and supervise. She should insist on her patient going to the doctor at the third and eighth months, and see her at regular intervals throughout the pregnancy and test her urine. Prematurity was one of the main factors in the high mortality-rate. Moreover, there were many minor ailments such as constipation, varicose veins, fatigue, lax abdominal walls, &c., on which helpful advice could be given, and many parturition troubles could be avoided if every mother were protected from over-fatigue in the first stage of labour. In the puerperium the "handy woman" was a potential danger; she had no idea of the elements of asepsis nor of how to treat any difficulty that arose. It was no use to expect a reduction in the maternal or infantile mortality until skilled nursing of the puerperium could be provided. Often the infant was taken off the breast during these early days for want of sensible advice. To sum up, the contribution of the midwife to the problem was: Observation and education during pregnancy, immediate recognition of any abnormality during labour, and skilled nursing during the puerperium.

The Problems in Rural Areas.

Dr. F. E. Fremantle spoke of the problem in rural areas. The days of the uneducated midwife, he said, were now over, yet some of the least educated midwives had got the best results by the exercise of homely common-sense. He warned the audience not to apply town ideas to country districts. Life in a village was simpler in many ways, and it was necessary to consider the community as a whole. There the doctor reigned supreme, and rightly so, deputing as much responsibility as he possibly could. The essentials of public health lay in the individual. The individual woman had it very largely in her own hands to prevent the disasters of her confinements. While the doctor might be the commanding officer in the campaign for the new life, the sergeant-major was undoubtedly the mother. Therefore, the first essential was to educate mothers, and at no time were they so receptive as during and especially just after their first pregnancy. Moreover, the girls should be taught from schooldays what their maternal function meant and the outlines of its hygiene treatment. To make rural midwifery attractive to suitable women the only satisfactory scheme would be to combine the services of district nursing, including tuberculosis nursing and care of the blind, with midwifery, school nursing, and health visiting. There was a definite future to offer to such women provided the public saw to it that the terms of service were adequate. Permanent quarters ought to be maintained for the nurse in the village. It was just as essential for the village to have a nurse as a parson, and as in the past it had been a public duty to endow the living of the parson so in modern times might the home, if not the salary, of the village nurse be endowed.

The Urban Problem.

Sir John Robertson contributed a paper dealing with large centres, which was read by the chairman. He pointed out how different the situation was in towns, where the midwife could get help in a few minutes and could attend lectures and other forms of instruction; where she could earn more in her more compact practice and pick her patients. He doubted, however, whether the position were really better, although undoubtedly easier and more attractive. There was much value in being thrown back on one's own resources. He urged the recognition of strict etiquette between doctors and midwives. The midwives were fighting the question of unqualified practitioners and ought to be supported by law, but unfortunately a great proportion of their work was done by doctors assisted by "handy women." The midwives ought to be able to send their patients into homes where they could attend them; at present a patient sent into a home was lost to the midwife.

Miss Liddiard, matron of the School of Mothercraft, said that the best educated woman was not doing midwifery because the remuneration was not safe. Country dwellers were often difficult to teach; often the midwife was the only person who could give real education. She believed confinement in the home to be the right thing. Labour was a natural process; why should it be made unnatural by taking the woman away from her husband and family? Moreover, the woman confined in hospital returned without having learned how to manage her baby in home conditions.

Miss Rosalind Paget said that the maternal mortality in 1924 was 1·5 per 1000 in rural areas and under properly-trained and supervised midwives. The women died; we did not know why they died, and that was what we had to find out. There should be post-mortem examinations on every fatal puerperal case. Often the post-mortem findings were clear enough, but were quite different from the diagnosis reached before death. The midwife could help by educating public opinion on the importance of autopsies. The examinations should be performed by competent obstetricians, preferably an official for the district. She also urged a uniform system of birth notification with a space to show clearly who it was that actually delivered the child.

Miss Olive Haydon said that the nursing of the puerperium had been neglected in the enthusiasm for ante-natal care. There were still registered midwives who were incapable of taking pulse or temperature. The mortality-rate could be reduced by careful adherence to the rules of the Central Midwives Board. Post-certificate education should be compulsory, and a longer period of training would help to raise the standard of teaching. More preventive measures should be taught.

Dr. Eustace Hill said that coöperation between the doctor and the midwife was difficult to achieve. Until recently only 19 per cent. of the cases in his district were attended by midwives, but the figure was now increased to over 35 per cent. One of the difficulties in the midwives' service was the opposition of the general practitioner. In one mining district where the public health authority had tried to establish a midwife the doctors had said frankly that they would do their best to starve her out. The two chief causes of maternal mortality were ignorance and the indiscriminate use of forceps. The general practitioner must be educated and also the individual patient on the importance of ante-natal care and the hygiene of labour and the puerperium. Another difficulty in the way of the midwife was that the fee for a doctor called in by a midwife was collected partly or wholly from the patient and might total three guineas, whereas for one guinea the doctor could be retained without a midwife. The patient should not be responsible for fees due to a doctor called in by the midwife. The number of a midwife's cases should be limited; midwives who delivered 300 patients in a year obviously did not do their work properly.

Miss Elsie Hall, speaking as a practising midwife in a poor area of London, said that the midwife had a unique opportunity to encourage husbands to come for an educational talk when she was first booked. She urged that boys and girls should be taught physiology in their schooldays.

Dr. Annie McCall urged the importance of post-mortem examinations. The mortality was high in the general practitioner's work, but much lower in hospitals and in the work of midwives. Doctors had often been sent for too early by midwives because midwives were not taught to do their internal examinations properly. This meant early and unnecessary forceps. She urged the necessity of allowing midwives to give sedative drugs to ensure an easy first stage. She had never seen any harm result from the use of chloral.

Dr. Harold Scurfield said that there was much talk about ante-natal work, but as a matter of fact very little was going on in the country at present. Women would not yet go for ante-natal advice, and must be educated by midwives on its necessity. But the doctor to whom they were sent must not be just any doctor, but a skilled obstetrician, and panels of obstetricians should be compiled. In America the experiment had been tried of putting all the midwifery of a district into the hands of the midwives, backed up by obstetricians. The mortality-rate fell at once. In Australia, where more confinements were conducted by midwives than in any other country, there were fewest maternal deaths. Most of the high maternal mortality was due to meddlesome midwifery.

Dr. R. E. McKenzie said that in Woolwich there was very good coöperation between midwives and the public health authorities. The midwives sent their cases to the ante-natal centres for advice. The trouble about ante-natal work was that there were no fees for it. Midwives had told her that the L.C.C.'s plan of paying the fee of a doctor called in by a midwife had made matters worse, because before that rule the doctor would come and do what was needed for a very small fee, but now the authority fixed a fee and extracted a part of it from the patient, who never knew what she would have to pay.

Sir Francis Champneys agreed that home was the best place for a normal labour. The woman's home ought to be one that she could be confined in, and that was the ideal to work for. To deny sedatives was inhuman. Opium was an excellent drug and appeared to act as a stimulant or as a sedative, according to the needs of the patient.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Public Health and Political Stability.

THE overthrow of ministries has its bearing on public health achievement. Here in France technical instruction in public health and popular hygiene is unquestionably good, but its general application throughout the country is poor, as is indeed frankly admitted. Ministerial changes may lie at the root of this failure. Any national accomplishment in public health depends upon the insistent promotion of a definite programme. In England and America the public health programme is only slightly affected by political change. In France the centralised governmental organisation has been unable to continue work along any programme on account of frequent reshuffling in the politico-social system. Leadership in the French public health services has been changed six times during the period 1914–1925. The longest time during which any chief has enjoyed office has been one year and a half; one remained but five months. Anyone familiar with the prolonged period necessary for raising the public health standard of a community will appreciate the effect on a really good public health programme of such frequent political change. As things are these programmes have a hard enough time at the hands of interested politicians.

Small-pox in France.

Vague reports of virulent outbreaks of small-pox in this country seem to have made British visitors thoughtful about choosing their autumn tour, and the British Embassy in Paris is said to have inquired in what departments of France tourists may travel freely without risks of infection. In reply it has been stated semi-officially that measures against small-pox are perhaps more effective in France than in any country. Free vaccination is practised in all the hospitals. Vaccination is compulsory in early childhood, among school children, in the army and navy, in hospitals and asylums, and a provision exists for making vaccination and revaccination obligatory in face of epidemic risk. Prompt application of isolation and vaccination has been found to control such recent outbreaks as that of 29 cases occurring at Toulouse, and that of 23 cases in the Hérault département. Four-fifths of the cases occurred in women who had not been revaccinated since childhood, and the mortality was 33 per cent.

The Bergonié Foundation.

The friends of the late Prof. Bergonié are collecting a memorial fund to be used in establishing a laboratory for electrical and radiological research and experiment. If the funds collected suffice, allowances for specially qualified investigators will be provided, in order that studies of this kind may be encouraged. It is also intended to supply modest pensions for workers disabled by work in electricity, or involving radium and X rays. Those desiring to contribute to this fund should communicate with the Fondation Bergonié, 5 rue Saint Philippe du Roule, Paris.

Awards in Medicine by the Académie des Sciences.

Notable awards in the medical and other sciences were made by the Académie des Sciences of the Institut de France, at its meetings of Oct. 26th and Nov. 3rd. Among the more important were the following: 5000 francs to Gaston Ramon, for work on anatoxins, especially the diphtheric anatoxin; 2500 francs each to Eugene Wollmann, for work on proteolysis and the defence ferments of Abderhalden; to Maurice Javillier (biological chemistry), to Léon Bérard and Charles Dunet, of Lyons (thyroid cancer), and to the group consisting of Sergent, Donatien, Parrot, Lestoquard, Plantureux and Rougebief (the bovine piroplasmoses of Algeria). Awards of 2000, 1500, 1000 francs and less were made to Mercier, Savigny, Rosenthal, Métalnikov, and others for their contributions to anatomy, zoology, blood transfusion, intracellular and protozoan activity.

Reduction of Infant Mortality.

Infant feeding centres are increasing in France. Their work includes supervision of artificially fed infants, together with regular examinations and effective utilisation of wet nurses. In 1922 and 1923 the movement was initiated by private agencies operating at six points outside Paris. Results were so satisfactory that the Assistance Publique has instituted centres at Montluçon, Moulins, Nevers, Toucy, and La Châtre; these care for a total of 280 infants. A private centre at Mainville has also been transferred to the Assistance Publique. For the private centres, a mortality of 16·7 per cent. in 1924 was lowered to 12·7 per cent. in 1925. For the official centres at Paris over the same period the diminution was from 12·3 per cent. to 11·3 per cent. A buffet providing sterile milk for infants, recently established in the railway station at Limoges, has proved so useful that similar buffets will be instituted at Nantes, Tours, St. Pierre-des-Corps, Montluçon, Périgueux, Vierzon, and Les Aubrais. These milk buffets are operated by the railway company of the Paris-Orléans region.

The Parents' Association of the Deaf-Mutes Institution in Paris has presented a vigorous protest against its projected removal to some provincial site. The protest will be considered by the Paris Municipal Council.

A new clinic for mental and neurological hygiene, sponsored especially by Profs. Claude and Nobécourt, and mainly devoted to children and adolescents, has just been established in the rue Vaugirard, not far from the Montparnasse railway station. The clinic provides examination, treatment, hospitalisation, and other aid which may be necessary, and will also be utilised for the instruction of medical students.

At a recent meeting of the Academy, Prof. Achard, on the completion of his five years' period as general secretary of the Académie de Médecine, was unanimously re-elected for another term of five years.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

The Council of Physical Therapy.

AT the recent Atlantic City meeting of the American Medical Association the trustees of the Association were empowered to set up a council to investigate and report on the merits of non-medicinal apparatus and contrivances offered for sale to physicians or hospitals. No time was lost, and a council, constituted on the lines of the Council of Pharmacy and Chemistry, has just met at Chicago. This council consists of two physicists, two physiologists, two pathologists, and four clinicians, whose names carry weight both at home and abroad. The council which, as yet, has simply discussed the scope of its work, intends not only to investigate physical apparatus, but to inquire into methods of massage, manipulation, hydrotherapy, and remedial exercises, and in the first instance a statement will be prepared of the present status of the various physical therapeutic methods now in use. American practitioners are hopeful of obtaining, through the advice of the council, value for their money.

Diphtheria Prevention.

Until recently the prophylactic use of diphtheria toxin-antitoxin has been almost limited to children of school age. These are naturally the most accessible to the health authorities and can be treated economically by routine methods. Parents in the U.S.A. are accustomed to having vaccination enforced at the school age and an additional measure of prevention comes naturally at this time. In New York City, where the largest numbers of school-children have been treated, there has been a definite fall in the mortality from diphtheria, and though it is hard to say how much this fall is directly due to the use of toxin-antitoxin, the authorities claim that the practice has saved the lives of 700 children since 1914. Considering, however, that more than half the deaths from diphtheria occur before school age is reached and that early diagnosis is most difficult in the pre-school years, it has seemed scarcely adequate to protect only the school-children. Where clinics are held regularly for pre-school children an obvious opportunity exists. Baltimore has had such clinics for several years and has lately taken advantage of them to make toxin-antitoxin immunisation available. As the result of publicity, no doubt, it has now been found necessary to open 12 new stations, and the attendance at these has been most gratifying, from 50 to 100 babies being reported as a weekly average from several of the new stations. At Syracuse, N.Y., where the Milbank Foundation is financing a health demonstration, special clinics are being held for the same purpose, and several pamphlets have been published for popular enlightenment. Copies of them can be obtained from the Syracuse Department of Health, 314, East Fayette-street, Syracuse, N.Y.

Increasing Virulence of Small-pox.

For cities in the United States and Canada in 1924 and 1923 the fatality-rates of small-pox were 1·5 per cent. and less than 1 per cent. respectively; but in the first six months of this year the figure has risen to 3·5 per cent. The fatality-rate for States and provinces (including the rural areas) has reached 2·1 per cent., which is three times that for 1923. The highest rate was in Camden, New Jersey, which reports 97 cases with 44 deaths. The statistical bulletin of the Metropolitan Life Insurance Co., in reporting these figures, predicts that "only thoroughgoing vaccination will protect the American and Canadian populations from an epidemic of deadly small-pox which, under present conditions of indifference to vaccination, bids fair to rival the most destructive small-pox epidemics in public history."

A Scheme of Neurological Convalescence.

The Public Health Committee of the New York Academy of Medicine has been considering the care of various types of convalescent patient. The subcommittee concerned with nervous cases point out that very few neurological cases run a clear-cut course ending in cure, and that the line of demarcation between the subacute and chronic is ill-defined. It is therefore impossible to confine any scheme strictly to convalescence and their proposals include all neurological cases save the really acute. The plan they put forward suggests that there should be four types of home. The first is the general convalescent home as it already exists, in which might be received cases such as peripheral neuritis, mild poliomyelitis, and surgical operations on the brain and cord. A variant of this would be a home more especially adapted to the neurological patient where a resident physician and nurses with some special training would deal with a small number of organic neurological cases and a few functional ones, included with a larger number of ordinary medical and surgical patients. The second type of house would be a new organisation specially run for neurological convalescents, such as choreas, early amyotrophies, neuritis and post-encephalitic cases, residual vascular cases, mild endocrinopathies, and early but already treated neurosyphilitics. A minority of general medical cases would be included in the home in order to improve the morale. Emphasis would be laid on recreations, games, and occupational therapy with a minimum of medicine. The third large type is the neurological convalescent farm, to which is attached a staff of specially trained nurses under a resident physician. This would accommodate exclusively functional cases, and emphasis would be laid on practical occupation, household, gardening, and farm work. Separate establishments should be reserved for behaviour children, including post-encephalitics. The fourth type is the hospital for chronic cases, working in conjunction with the convalescent system. The majority of the patients would require only custodial care, but a few would be admitted for medical study and diagnosis in order to improve the atmosphere of the institution. Stress would be laid on medicinal treatment and physiotherapy and recreations should be supplemented by occupation therapy. The only place for the epileptic would be in a special neurological convalescent home or a chronic hospital reserved for this type of case. The report of the subcommittee concludes with the statement that 5900 prospective patients per annum would probably benefit by the coördination in New York of convalescent homes on the lines indicated.

Obituary.

FREDERICK ST. GEORGE MIVART,

M.D. LOUVAIN, F.R.C.S. EDIN.

Dr. F. St. George Mivart, formerly medical officer of the Ministry of Health, died suddenly at his London residence on Nov. 5th at the age of 70. A son of Dr. St. George Mivart, F.R.S., who was a zoologist of more than European reputation, he was educated at Beaumont and the Catholic College of Higher Studies, Kensington. He received his medical training at St. Mary's Hospital, London, and at the Royal Infirmary, Edinburgh, qualifying in 1881 as M.R.C.S. Eng. and L.R.C.P. Edin. Three years later he was admitted to the Fellowship of the Royal College of Surgeons of Edinburgh, and after study in Paris, Vienna, and Louvain he gained, in 1889, the M.D. Louvain. After holding in London the successive posts of house surgeon to the Male Lock Hospital and surgeon to the City Dispensary and Western General Dispensary, he was appointed as medical officer to the Local Government Board, and subsequently to the Ministry of Health.

A colleague in the Ministry of Health sends the following appreciation: "Yet another gap has been made in the already small number who remain of the medical inspectors appointed to the Local Government Board in the last decade of the nineteenth century. Mivart joined the staff when he was about 42, and brought to the work a fine and matured intellect, ripened by experience at home and abroad, and among the great men whose colleague he became Mivart soon made his own distinctive impression. He was not a 'specialist,' as was Parsons, on the then somewhat unsettled isolation hospital question or as Power on epidemiology, or as Copeman in scientific research, but no one was more fit to maintain the dignity of the Government Office to which he belonged than Mivart; none knew better than he how to 'admonish' the neglectful official, not by bludgeoning, but in the manner of expert fencer. Mivart ever expressed his accurate observations and thoughtful deductions in careful and felicitous English, and many articles from his pen were printed in the series of reports by medical officers of the Local Government Board on public health subjects. The matter of several of Mivart's reports was so striking as to be given wide publicity in the lay press. To the end of his life Mivart kept up a practical interest in public health work, for, since his retirement some six years ago, he had been a councillor of the Royal Borough of Kensington and a Poor-law guardian. Quite recently he spoke of revisiting with myself the scene of one of his early labours, in order to find out for himself what progress had been made in impounding as a public water-supply certain plentiful springs to which his attention had been drawn years before. Like many another project this was never fulfilled. After passing more than the Psalmist's span of life, he has gone to his rest while still in harness, leaving children, a grandchild, and a great-grandchild to mourn his loss with his widow."

He married, in 1877, Marie Sofie, daughter of Mr. D. Maurigny, of Nice, France, and to her we express our sympathy.

WILLIAM EDWARD NICHOLLS DUNN,

M.B. LOND., M.R.C.S. ENG.

Dr. Nicholls Dunn, who died at Mentone on Oct. 9th after a long illness, was born at Usk, Monmouthshire, in 1871. He was educated at Monmouth Grammar School where he excelled at both cricket and football. He went to St. Bartholomew's Hospital in 1889, took his medical qualification in 1895, and then held resident appointments at the Metropolitan and Queen Charlotte's Lying-in Hospitals, serving also as house physician and resident anæsthetist at St. Bartholomew's. During the South African War he served as civil surgeon to H.M. Hospital Ship *Nubia*, and at the end of the war, owing to indifferent health, he began to winter in Egypt, where he became well known, first as medical officer in Messrs. Thos. Cook and Son's Nile Service and later as resident in Luxor. Here he did good work amongst the visitors and gave much time to the Luxor Hospital for Natives. Shortly after the Great War broke out Dunn volunteered and entered the R.A.M.C., in which he worked devotedly from 1915–19 at Netley Hospital and the Horton Hospital at Epsom. It was this work and the worry and anxiety attached to it, his friends think, that was responsible for the lighting up of the chest trouble which had threatened him for nearly 30 years. He again wintered in Egypt, 1920–22, but was never the same man as before.

"Bill Dunn," writes one of his friends, "was always a favourite with his fellow students and resident officers, but it was in Luxor that I learned to know him well. He was a first-rate practitioner and good anæsthetist. He had his ideals, was a staunch, kind friend, and a very faithful colleague. He was very jealous of the good name of the profession and very plain-spoken about anything he considered unworthy or not altogether straight and upright. In spite of the ill-health which dogged his footsteps, he made a name at Luxor amongst his patients, both British and American. With the natives of Egypt he was a favourite. In whatever sphere he worked he would have made his mark. His numerous friends will much regret his loss."

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED OCT. 31ST, 1925.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 98 (including 14 new cases at Sheffield, 16 at Sutton-in-Ashfield, Notts, and 25 at Blagdon, Durham); scarlet fever, 2588; diphtheria, 1177; enteric fever, 87; pneumonia, 1100; puerperal fever, 44; cerebro-spinal fever, 7; acute poliomyelitis, 13; acute polio-encephalitis, 1; encephalitis lethargica, 52; dysentery, 1; ophthalmia neonatorum, 110. There were no cases of cholera, plague, or typhus notified during the week.

Deaths.—In the aggregate of great towns, including London, there were 5 deaths from enteric fever, 30 from measles, 8 from scarlet fever, 12 from whooping-cough, 31 from diphtheria, and 54 from influenza. In London itself there were 7 deaths from diphtheria, 13 from influenza, and 24 deaths of infants under two years of age from diarrhœa and enteritis.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

C. W. Keates to *Cambrian*.

Surg. Lt. (R.N.V.R.) L. P. Spero has been entered as Surg. Lt. and has been appointed to the R.N. Hospital, Haslar, for course.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. B. A. Craig retires on ret. pay.

Capt. J. E. Measham retires, receiving a gratuity.

R. J. G. Hyde to be temp. Lt.

TERRITORIAL ARMY.

Maj. W. H. Broad, having attained the age limit, is retd. and retains his rank with permission to wear the prescribed uniform.

Capt. F. B. Julian resigns his commn. and retains his rank.

Lt. W. R. S. Watkins to be Capt.

Lt. V. S. Mitcheson (late R.A., T.A.) to be Lt.

General List (Supernumerary): Capt. F. Hauxwell to be Maj.

Capt. F. C. Chandler, R.A.M.C., to be Divisional Adjutant, 51st (Highland) Divisional T.A., vice Capt. T. L. Fraser, R.A.M.C., who vacates that appt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Lt.-Col. (Bt.-Col.) G. C. E. Simpson, from Active List, to be Lt.-Col. (Bt.-Col.).

TERRITORIAL DECORATION.

The King has conferred the Territorial Decoration upon the undermentioned officers: Lt.-Cols. C. H. S. Redmond and E. B. Bird, and Majs. C. Corfield, W. J. Harrison, and A. F. Lee.

INDIAN MEDICAL SERVICE.

The King has approved the retirement of Lt.-Col. F. S. C. Thompson.

The King has also approved the relinquishment of their temporary commissions by Capts. Nur Ahmed Quraishi and Chuni Lal Khanna.

Maj. J. W. Jones has been appointed Civil Surgeon, Maymyo. Dr. F. Reynolds officiates as Civil Surgeon, Ruby Mines District. Lt.-Col. J. E. Clements has been appointed Inspector-General of Prisons, United Provinces, vice Lt.-Col. J. M. Woolley, retired. Lt.-Col. M. R. C. MacWatters, civil surgeon, Meerut, has been appointed to the civil medical charge of the Saharanpur District, vice Maj. A. Seddon, reverted to military duty. Lt.-Col. Herbert Hallilay, late civil surgeon, Murree, has been appointed to act as Civil Surgeon, Simla (West), vice Lt.-Col. W. W. Jeudwine. Capt. S. N. Hayes has been posted to Dalhousie as Civil Surgeon in relief of Capt. G. E. L. Simons. Lt.-Col. W. J. Powell, Inspector-General of Prisons, Central Provinces, has been appointed Civil Surgeon, Pachmarhi. Col. P. Dee, hon. surg. to the King, the senior I.M.S. colonel on the active list, has retired and has been succeeded by Col. A. Fenton, late civil surgeon at Mandalay. Capt. S. C. Contractor has been appointed to the Jail Department, Madras. Lt.-Col, F. P. Warwick has been reposted as Civil Surgeon, Amraoti, on return from leave. Maj. G. H. Mahony has been appointed Civil Surgeon and Superintendent of the Jail at Saugor. Lt.-Col. C. A. Sprawson has resumed his appointment as Principal of King George's Medical College, Lucknow. Maj. A. Seddon, civil surgeon, Saharanpur, has reverted to military employment.

DEATHS IN THE SERVICES.

Surg.-General Howard James McChleary Todd, C.B., R.N., hon. surgeon to the King, who died suddenly at Gosport, Hants, on Nov. 6th, was born on Sept. 20th, 1855. He was the son of Mr. M. G. Todd, of Hove, and was educated at Dr. Seaver's School at Brighton, and at St. Thomas's Hospital where he was a prizeman. He entered the Naval Medical Service in 1876 and was in medical charge with the Niger Expedition in 1879. For his services during the yellow fever epidemic at Jamaica in 1885–86 he received the thanks of the Admiralty, and in 1891 he was thanked by the Foreign Office for his services as acting Consular surgeon at Mapanda's Kraal. Surg.-General Todd married in 1893 Florence Agnes, daughter of Mr. E. Haynes, of Thimbleby, Yorks, by whom he had one son and two daughters.

LIVERPOOL'S ACID RAIN.—During the last year 615 tons of organic matter—nitrates, bitumen, calcium salts, sulphates, and chlorides—came down with the rain on each square mile of Liverpool's most densely populated districts. The bronze of the Queen Victoria monument at the end of Lord-street has been so acted on by the sulphuric acid in the rain-water that the copper sulphate formed has sunk to a distance of 4 inches in the Portland stone on which the monument stands.

Medical News.

University of Oxford: *Hospital Scholarships.*—Entrance scholarships and exhibitions have recently been awarded to the undermentioned members of the Oxford Medical School at the hospitals named:—Guy's Hospital: O. A. Beadle, New Coll.; L. T. Ride, New Coll. King's College Hospital: C. F. J. Cropper, University; A. W. Cubitt, Wadham; W. G. Rees, Jesus. St. George's Hospital: H. E. Mansell, Pembroke. St. Mary's Hospital: D. H. Brinton, New Coll.; W. Hurst Brown, Queen's. Westminster Hospital: W. R. Greene, Pembroke; A. T. Leslie Spinks, Oriel; M. G. Pearson, Keble; H. G. Wells, Magdalen.

Chelsea Clinical Society.—A meeting of this Society will be held in the Board Room of St. George's Hospital on Nov. 17th, at 8.30 P.M., when insulin treatment will be discussed by the following speakers, among others: Drs. E. P. Poulton, George Graham, P. J. Cammidge, and F. G. Crookshank.

Royal Medico-Psychological Association.—The next quarterly meeting of the Association will take place at 2.30 P.M. on Tuesday, Nov. 17th, at 11, Chandos-street, Cavendish-square, London, W. 1, under the presidency of Sir Frederick Mott. Dr. J. Carswell will open a discussion on Insanity and Crime: Some Suggestions arising out of the Atkin Report.

Royal Commission on National Health Insurance.—The forty-fourth meeting of the Commission was held at the Home Office, Whitehall, on Nov. 5th and 6th, Lord Lawrence of Kingsgate and later Sir Arthur Worley in the chair. Evidence was given by Sir William Glyn-Jones as to the powers and duties of insurance committees and the limited field of work open to them under the conditions of the insurance scheme as it has now developed. Thereafter the Commission sat in private to review the evidence which has been received since it began its work and to consider the questions arising therefrom.

Royal Society.—Among the honours conferred this year by the Royal Society are a royal medal to Prof. W. H. Perkins, F.R.S., for work on the constitution of the alkaloids; the Davy Medal to Sir James Irvine, F.R.S., for his work on the constitution of the sugars; the Hughes Medal to Mr. F. E. Smith, F.R.S., for his determination of fundamental electrical units and for researches in technical electricity. Prof. A. Einstein, foreign member R.S., has been awarded the Copley Medal for his theory of relativity and his contributions to the quantum theory. The following have been recommended by the President and Council for election to the Council at the anniversary meeting on Nov. 30th:—President: Sir Ernest Rutherford. Treasurer: Sir David Prain. Secretaries: Mr. J. H. Jeans and Dr. H. H. Dale. Foreign Secretary: Sir Richard Glazebrook. Other Members of Council: Prof. J. H. Ashworth, Prof. L. Bairstow, Prof. F. O. Bower, Prof. S. Chapman, Sir Dugald Clerk, Prof. F. G. Donnan, Prof. E. J. Garwood, Prof. J. P. Hill, Prof. J. B. Leathes, Prof. J. C. G. Ledingham, Sir Thomas Lewis, Prof. F. A. Lindemann, Sir Robert Robertson, Sir Charles Sherrington, Dr. G. C. Simpson, and Mr. W. C. D. Whetham.

Fellowship of Medicine and Post-Graduate Medical Association.—On Monday, Nov. 16th, at 5.30 P.M. Sir Henry Gauvain will lecture for the Fellowship of Medicine on Light Treatment of Surgical Tuberculosis in the Lecture Hall of the Medical Society of London, 11, Chandos-street. This lecture is open to all members of the medical profession. The West End Hospital for Nervous Diseases will hold a three weeks' course from Nov. 23rd, dealing with the diagnosis and treatment of nervous diseases. The lecture-demonstrations will be given at 5 P.M. in the Out-patient Department, 73, Welbeck-street, W. 1. From Nov. 23rd to Dec. 12th the Royal Waterloo Hospital will hold a course in medicine, surgery, and gynæcology, covering all departments pertaining to diseases of women and children. For the convenience of the general practitioner whose available time is limited, the London Temperance Hospital has arranged a late afternoon course (4.30 to 6 o'clock) in general medicine, surgery, and the specialties, from Nov. 23rd to Dec. 4th. There will be a special course at the Infants Hospital from Nov. 30th to Dec. 13th. In December there will be the following special courses: Dermatology, Dec. 7th to 19th, at the Blackfriars Skin Hospital, and a similar afternoon course (4.30 to 6.30) at the Hampstead General Hospital from Dec. 7th to 19th. A copy of each syllabus and the Fellowship general course programme will be forwarded on application to the Secretary of the Fellowship of Medicine, 1, Wimpole-street, London, W. 1.

The death is announced from Habana of Dr. Juan Guiteras, pathologist and hygienist, at the age of 74 years. His study of yellow fever in Cuba is well known.

Tuberculosis Society.—A meeting of this society will be held at 1, Upper Montague-street, Russell-square, London, on Friday, Nov. 20th, at 8 P.M., when Dr. A. Sandison will read a paper on Swiss Sanatoria from the English Standpoint.

Royal Statistical Society.—The first meeting of the session will be held on Tuesday, Nov. 17th, at 5.15 P.M., at the Royal Society of Arts, John-street, W.C. 2, when Mr. G. Udny Yule, F.R.S., will read his presidential address: "Why do we Sometimes get Nonsense-correlations before Time Series? A Study in Sampling and the Nature of Time Series."

The Glasgow University Club, London, will dine at the Trocadero Restaurant, Piccadilly, on the evening of Friday, Dec. 4th, when Sir Henry Craik, M.P., will preside. Any Glasgow University men who, though not members of the Club, would like to attend should communicate with the Hon. Secretaries, 1, Harley-place, London, N.W. 1.

Temporary Home of the Foundling Hospital.—The governors of the Foundling Hospital have purchased the Royal St. Anne's Schools at Redhill as a home for the institution pending the acquisition of a new property and the erection upon it of the necessary buildings.

Model Abattoir Society.—The fourth annual Benjamin Ward Richardson Memorial Lecture will be delivered on Friday, Nov. 20th, at 5.30 P.M., in the Lecture Hall of the Royal Society of Medicine, 1, Wimpole-street, W. 1, by Dr. William J. Howarth, medical officer of health, City of London, on the Slaughtering of Animals for Human Consumption. The lecturer will deal with methods practised, desirability of centralisation in relation to meat hygiene, and the avoidance of cruelty. Admission is free, without tickets.

Royal Faculty of Physicians and Surgeons of Glasgow.—At the annual meeting of the Royal Faculty held on Nov. 3rd the following officers were elected for the years 1925 and 1926:—President: Mr. R. M. Buchanan; Visitor: Dr. G. H. Edington; Treasurer: Mr. J. H. MacDonald; Hon. Librarian: Dr. E. H. L. Oliphant; and Dr. James A. Adams, Dr. A. Freeland Fergus, Dr. J. M. Munro Kerr, Mr. Thomas Kay, Mr. Archibald Young, Dr. John Henderson, Dr. H. L. G. Leask, Mr. R. Barclay Ness, Dr. W. G. Dun, and Mr. J. Forbes Webster were appointed councillors.

Glasgow Victoria Infirmary.—Towards the £100,000 required for the extensions that are being made, £57,000 has been subscribed, but by fewer than 200 persons, and an intensive appeal for the balance is now being made. The extensions include new operating theatres and a new nurses' home. The infirmary, which was founded 35 years ago with 84 beds and cots, now has 260, and treats ten times the number of patients whom it succoured in 1890.

Torbay Hospital.—Last week the freedom of the borough of Torquay was conferred upon Mrs. Francis Rowcroft in recognition of her gift of £100,000 for the erection of the new Torbay Hospital. She and her sister, Mrs. Wills, have between them given £123,000 for this purpose. These ladies are the grand-daughters of the late Sir Edward Payson Wills, Bart., of the firm of W. D. and H. O. Wills.

Overcrowded Mental Hospitals.—At the last meeting of the Staffordshire Mental Hospitals Board it was reported that the three mental hospitals in the county are all overcrowded. At Burntwood there are 146, at Cheddleton 66, and at Stafford between 30 and 40 patients in excess of the authorised numbers. It was complained that the boards of guardians were sending many mild cases which might well be treated in their own institutions.

The late Dr. G. L. Pardington.—George Lucas Pardington, M.D. Durh., M.R.C.P., who died on Nov. 1st, was one of the oldest medical practitioners in Tunbridge Wells. A Gloucestershire man, he studied medicine at St. Bartholomew's Hospital, qualifying in 1878 and taking the M.B. Durh. two years later. In 1903 he was admitted to the Membership of the Royal College of Physicians. After a short stay in London he settled at Tunbridge Wells, where he had an extensive general practice, which as time went on became more of a consultant character; he was for many years on the honorary staff of the Tunbridge Wells General Hospital. Dr. Pardington was specially interested in climatic problems, of which he had made some little study at home and abroad; he was a member of the Council of the Balneological Section of the Royal Society of Medicine. His contributions to the medical press covered a wide field of clinical problems.

PADDINGTON HOSPITALS.—The four hospitals in the borough of Paddington are burdened by debts amounting to about £50,000, and a determined attempt is being made to place them in a more stable position. St. Mary's spends £60,000 a year and its assured income is only one-third of that sum. The Children's Hospital admits nearly 900 patients a year to its wards. The venerable London Lock Hospital, the pioneer in the treatment of venereal disease, is hampered by insufficient income and an increasing debt, and the Paddington Tuberculosis Dispensary, which claims to have been the first of its kind in England, also needs help.

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the committee 71 cases were considered and £658 voted to 54 applicants. The following is a summary of some of the new cases relieved :—

L.R.C.P. Edin., 1888, aged 73. Met with a motor-bicycle accident while acting as assistant to a doctor and broke both legs and his right clavicle. A doctor at the hospital approached the Fund with a view to getting him away to a convalescent home. An emergency grant of £10 was sent to be used for the applicant's benefit ; a further £6 was voted.

M.R.C.S. Eng., 1869, aged 80, who practised in Berkshire and retired. Married and has two children. Investments have failed and applicant, wife, and youngest daughter, aged 47, are now living on money received by the sale of household goods. This case has been investigated through the Guild and the report states that they live in a dingy old house which has a mortgage on it for £730. The interest on this and rates amount to £52 per annum. The eldest daughter, aged 51, is a widow and she is maintained by her son, so cannot render any assistance to her father and mother. An emergency grant of £5 was sent and the Committee voted £40 in 12 monthly instalments.

Widow, aged 68, of M.R.C.P.I., 1880, who practised for 20 years in Wales and died in 1898. Applicant is a trained nurse and has supported herself since her husband's death. She has just had an operation for cataract and is asking for assistance as she has no means and is not yet old enough for the Old Age Pension. £5 was sent as an emergency grant, and a further £5 was voted.

L.S.A., 1884, aged 62, who prior to the war was a ship's surgeon. Served during the war, 1914 to 1923, when he was demobilised from the R.A.M.C., Ireland. Since has made a small income by taking locums. In February last was ill and unable to get further employment, and owing to events in Ireland came to the end of his resources. His wife left him in 1922. November, 1924, Officers' Association gave £5 to enable him to take a post and again in September, 1925, a further £5 was given to his sister for his benefit. As the applicant was very ill he was admitted to King's College Hospital, and when better the Fund was approached with a view to getting him away to a convalescent home. The Fund gave £2 12*s.* 6*d.* for this object.

M.D. Brux. and L.R.C.P. Edin., 1897, aged 57. Unable to get locums has applied to the Fund for assistance. During the last 12 months has received £105 from locums and has had, unfortunately, to apply to the guardians to live, who made an allowance for applicant and wife of 30*s.* a week from Sept. 11th. The rent of one room is 12*s.* 6*d.* a week. Our local secretary sends us a satisfactory report. On his recommendation £5 was sent at once.

Widow, aged 56, of L.R.C.P. Lond. who practised in London and died in July. The late doctor gave up his practice during the war and was unable to take it up again. They had resident patients who were looked after and nursed by the applicant. From paying guests £137 was received during the last 12 months. The rent and rates amount to £90 per annum. The applicant is anxious to get rid of the responsibility of the house and will give it up at the end of this year. She is thoroughly domesticated and a good nurse, and hopes to get a post as housekeeper in a private family. Voted £15 in two instalments.

Widow, aged 85, of M.R.C.S. Eng., 1860, who practised in Lincolnshire and London and died in 1894. She is allowed to live with her daughter who is a housekeeper who earns £50 per annum. The applicant has the Old Age Pension and an allowance of £6 from her eldest son. Three other married sons unable to help. The applicant pays 5*s.* a week towards her board. Voted £30 in 12 monthly instalments.

Widow, aged 53, of M.D. Aberd., 1879, and died in August, who practised until incapacitated by paralysis. The three pensions died with him. Applicant now left without means and the only money in the home is paid by two daughters for their board and lodging at the rate of £1 a week each. Rent and rates are £42 per annum. Applicant's late husband was a pensioner of the Fund. Voted £10 in two instalments.

Widow, aged 68, of M.D. Glasg. who practised in Scotland and died in March, 1922. The long illness of the doctor crippled their resources, and since his death the applicant has tried to live on the income made by letting apartments in the summer. This summer she has only made £40. The cottage occupied is her own and she has to pay rates £17 per annum. A report from the Guild local secretary says it is a case deserving of financial help from the Fund. Voted £18 in 12 monthly instalments.

Widow, aged 58, of M.B. Edin. who was a medical superintendent at a hospiatl and died suddenly in August. A grant is asked to tide over the next few months while all business matters are being settled. Her probable income will contribute £35 towards her board. The applicant has had the house done up in order to let and has now succeeded in letting two rooms which will bring in £42 per annum. Rent and rates amount to £47 per annum. Applicant has no children. Voted £10.

Subscriptions may be sent to the honorary treasurer, Sir Charters Symonds, at 11, Chandos-street, Cavendish-square, W. 1.

THE LATE DR. R. R. JONES.—The death occurred at Bangor on Oct. 26th of Dr. Rees Rowland Jones in his sixty-ninth year. The son of a Cardiganshire farmer, he was educated at Durham University and the London Hospital, and became M.R.C.S. Eng. in 1880. He held house surgeon appointments at Newcastle and Bangor and settled in the latter town where he gained a large practice. He was an honorary medical officer and radiologist to the Carnarvonshire and Anglesey Infirmary and medical officer for the Bangor section of the Bangor and Beaumaris Union. Dr. Jones took a keen interest in local and national affairs and was deputy mayor of Bangor ; ill-health prevented his accepting the office of mayor. He was twice married, and leaves nine children.

SOCIETY OF MEMBERS OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At the annual meeting to be held at the College next Thursday, Nov. 19th, at 3 P.M., Dr. L. Haden Guest will move :

> "That this thirty-seventh annual meeting of Fellows and Members again affirms the desirability of admitting Members to direct representation upon the Council of the College, which, as now constituted, only represents those Members who also hold the Fellowship. It does so in order that the constitution of the Council of the Royal College of Surgeons of England shall be in keeping with modern ideas of true representation, and more in conformity with the present-day requirements of its Members and Fellows.
>
> "Further, that as the Royal College of Surgeons of England is composed of 19,147 persons, of whom no less than 17,361 are Members, the majority engaged in general practice, this annual meeting respectfully requests the Council (now about to apply to H.M. Privy Council for a supplementary Charter) to avail themselves of this special opportunity to insert a provision therein for some representation of Members, as such, upon the Council of the College, and so restore a right they enjoyed prior to the Charter of 1843."

The resolution will be supported by Dr. J. O'Donovan, Mr. M. J. Smyth, F.R.C.S., and Mr. F. Lawson Dodd, L.D.S.

LADY HARDINGE MEDICAL COLLEGE.—The Government of India has decided to raise its grant to the Lady Hardinge Medical College at Delhi from Rs.200,000 to Rs.310,000. It has also made a grant, for the current year only, of Rs.98,000 for equipment, and the stage of acute financial stringency through which the College has passed is thus satisfactorily ended. The increased grant will enable the College authorities to bring the whole of the attached hospital into use for the first time.

ST. BARTHOLOMEW'S HOSPITAL, ROCHESTER.—It has been decided to spend £80,000 in enlarging this hospital. Founded in 1078 and reconstituted in 1858, St. Bartholomew's claims to be the oldest foundation in the country. It is at present a hospital of 105 beds, but a further 50 beds are to be provided. The Dean of Rochester, the Governor, emphasises the pressure caused by the increase in the number of street accidents, and there are now more than 11,000 patients annually.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY, Burlington House, Piccadilly, W.

THURSDAY, Nov. 19th, 4.30 P.M.—*The following Papers will be Read :* J. W. Pickering and R. J. Gladstone : The Development of Blood Plasma. Part I. The Genesis of Coagulable Material in Embryo Chicks (communicated by Prof. W. D. Halliburton). D. J. Scourfield : On a New Type of Crustacean from the Old Red Sandstone (Rhynie Chert Bed, Aberdeenshire), Lepidocaris Rhyniensis (communicated by Dr. W. T. Calman). J. R. Norman : The Development of the Chondrocranium of the Eel (*Anguilla vulgaris*) with Observations on the Comparative Morphology and Development of the Chondrocranium in Bony Fishes (communicated by Prof. E. W. MacBride). J. Needham and Dorothy Needham : The Hydrogen-Ion Concentration and Oxidation-reduction Potential of the Cell-Interior before and after Fertilisation ; a Micro-Injection Study of Marine Eggs (communicated by Sir Frederick Hopkins). R. R. Armstrong : Studies on the Nature of the Immunity Reaction (communicated by Sir Frederick Andrewes) R. J. Ludford : The Cytology of Tar Tumours (communicated by Dr. J. A. Murray). Eric Ponder : The Inhibitory Effect of Blood Serum on Hæmolysis (communicated by Sir E. Sharpey Schafer). L. Brull and F. Eichholz : The Effects of Calcium and Potassium Ions on Urine Secretion as studied in the whole Animal (communicated by Prof. E. H. Starling). L. Brull and F. Eichholz : The Secretion of Inorganic Phosphate by the Kidney (communicated by Prof. E. H. Starling). F. Eichholz, R. Robison, and L. Brull : Hydrolysis of Phosphoric Esters by the Kidney *in vivo* (communicated by Prof. E. H. Starling).

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Monday, Nov. 16th.

THE DAVID LLOYD ROBERTS LECTURE: at 5.30 P.M.
This Lecture will be delivered by Sir Arthur Keith, on Man's Structural Defects.

Tuesday, Nov. 17th.

GENERAL MEETING OF FELLOWS: at 5.30 P.M.

PATHOLOGY: at 8.30 P.M.
Papers:
Mrs. M. M. Barratt: The Susceptibility of Rats and Mice to Diphtheroid Infections.
Miss D. B. Steabben: Further Experiments on the Action of Colloidal Substances.
Dr. C. Dukes: Early Stages in Cancer of the Rectum.

Wednesday, Nov. 18th.

HISTORY OF MEDICINE: In view of the date and time of the Thomas Vicary Lecture, the November Meeting of this Section is cancelled.

Thursday, Nov. 19th.

DERMATOLOGY: at 5 P.M. (Cases at 4 P.M.)
Cases will be shown.

Annual Dinner of the Society.

Hotel Victoria: 7.30 for 8 P.M.

Friday, Nov. 20th.

ELECTRO-THERAPEUTICS: at 8.30 P.M.
Cinematographic Demonstration:
Dr. L. D. Bailey: Recovery of Function after Nerve Anastomosis.
Demonstration of the
De Forrest Talking Films, with reference to their scope and possibilities in Medical Education. Introductory remarks by Dr. C. B. Heald.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.
Thursday, Nov. 19th.—8.15 P.M. (at the London School of Hygiene and Tropical Medicine, Endsleigh-gardens, Euston-road), Laboratory Meeting, at which, among others, the following will give demonstrations: Col. A. Alcock, Drs. Andrew Balfour, H. A. Baylis, Major K. K. Chatterji, Drs. Aldo Castellani, J. T. Duncan, Th. Jeekes, Prof. R. T. Leiper, Drs. H. B. Newham, H. H. Scott, Lieut.-Colonel H. Marrian Perry, Drs. N. A. Dyce Sharp, J. Gordon Thomson, and C. M. Wenyon.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.
Monday, Nov. 16th.—5.30 P.M. (at the Royal Society of Medicine, 1, Wimpole-street, W.), Sir Arthur Keith: Man's Structural Defects (Lloyd Roberts Lecture).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.
Wednesday, Nov. 18th.—5 P.M., Prof. William Wright: The Mediæval Conception of the Anatomy and Physiology of the Central Nervous System (Thomas Vicary Lecture).

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
Monday, Nov. 16th, to Saturday, Nov. 21st.—Fellowship of Medicine Lecture, Medical Society, 11, Chandos-street, W. Mon., 5.30, Sir Henry Gauvain: Light Treatment of Surgical Tuberculosis.—Chelsea Hospital for Women, Arthur-street, S.W. Post-graduate Course in Gynæcology. Lectures and Demonstrations daily. Operations and Pathology.—London Lock Hospital, Dean-street, W. Comprehensive Course, Instruction in the Out-patient Department and Lectures.—City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E. Special Course in Diseases of the Heart and Lungs. Lectures, Clinical Demonstrations, and Laboratory Demonstrations.—St. John's Hospital, Leicester-square, W.C. Daily Demonstrations in the Out-patient Department. Bi-weekly Lectures Tuesday and Thursday at 5.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
Thursday, Nov. 19th.—3 P.M., Mr. E. Miles Atkinson: Hearing Tests. 4.30 P.M., Dr. J. Metcalfe: The X Ray Examination of Pelvic Conditions.
Daily: In-patient and Out-patient Clinics in General and Special Departments, Operations, &c.

THE LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.
Tuesday, Nov. 17th.—5 P.M., Dr. A. Whitfield: Diseases due to Fungi (1).
Thursday.—5 P.M., Dr. R. F. Fagan: Pathological Demonstration.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.
Friday, Nov. 20th.—3 P.M., Mr. Watkyn-Thomas: An Intra-Cranial Case.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL, Marylebone-road, N.W.
Thursday, Nov. 19th.—5 P.M., Mr. Trevor B. Davies: Clinical Aspects of Abortion.

CHADWICK PUBLIC LECTURES.
Wednesday, Nov. 18th.—5.15 P.M. (in the Barnes Hall of the Royal Society of Medicine, 1, Wimpole-street), Sir Wilfred Beveridge: Insects in Relation to Public Health.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C.
POST-GRADUATE COURSE: October–November, 1925.
Clinical Lectures and Demonstrations.
Monday, Nov. 16th.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Papillœdema: Mr. Williamson Noble.
Tuesday, Nov. 17th.—2 P.M., Out-patient Clinic: Dr. Walshe. 3.30 P.M., Neurosyphilis: Dr. Hinds Howell.
Thursday, Nov. 19th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Method of Investigating the Eighth Nerve: Mr. Just.
Friday, Nov. 20th.—2 P.M., Out-patient Clinic: Dr. Adie. 3.30 P.M., Poliomyelitis: Dr. Collier.
The fee for the Course, including Pathology Lectures, is £5 5*s.* For those who hold Perpetual Tickets the fee is £3 3*s.*

Course of Lectures and Demonstrations on the Pathology of the Nervous System.
Thursday, Nov. 19th.—12 noon, Syphilis of Nervous System: Dr. J. G. Greenfield.

Course of Lectures and Demonstrations on the Anatomy and Physiology of the Nervous System.
Monday, Nov. 16th.—12 noon, The Cerebral Hemispheres: Dr. J. L. Birley.
Dr. H. J. Macbride is giving a Course of Eight Clinical Demonstrations, chiefly on Methods of Examination of the Nervous System, in the Wards at 10 A.M. on Tuesdays and Fridays. The fee for this Course is £2 2*s.*
Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.
Any part of the Course may be taken separately. Special arrangements will be made for those unable to take the whole Course.
Fees should be paid to the Secretary of the Hospital at the Office on entering for the Course.
J. G. Greenfield, Dean of Medical School.

MANCHESTER ROYAL INFIRMARY, POST-GRADUATE COURSE.
Tuesday, Nov. 17th.—4.15 P.M., Lloyd Roberts Lecture at St. Mary's Hospital. Dr. T. Watts Eden: What We Can Do for the Unborn Child.
Friday.—4.15 P.M., Prof. J. S. B. Stopford: The Sympathetic Nervous System.

ST. MARY'S HOSPITALS, Manchester.
Tuesday, Nov. 17th (at the Whitworth-street West branch), Dr. T. Watts Eden: What We Can Do for the Unborn Child (Lloyd Roberts Lecture).

ANCOATS HOSPITAL POST-GRADUATE LECTURES.
Thursday, Nov. 19th.—4.15 P.M., Mr. H. Platt: The Treatment of Common Fractures, with Practical Demonstrations.

JAMES MACKENZIE INSTITUTE FOR CLINICAL RESEARCH, ST. ANDREWS.
Tuesday, Nov. 17th.—4 P.M., Prof. Herring: The Use of Insulin.
Saturday.—12 noon, Prof. Murray Lyon and Assistants: Demonstration in the Royal Infirmary, Edinburgh.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.
Wednesday, Nov. 18th.—4 P.M., Dr. C. W. Saleeby: The Rôle of Clothing in the Prevention and Arrest of Disease.

Appointments.

Anderson, W. W., M.B., Ch.B. Edin., has been appointed Certifying Surgeon under the Factory and Workshop Acts for Whitchurch.

Gray, J. S. M'Lean, Assistant Tuberculosis Officer and Assistant Medical Officer of Health for Renfrew.

Tibbles, S. G., L.R.C.P., L.R.C.S. Edin., L.R.F.P.S. Glasg., Honorary Oculist to the Actors' Association and the Actors' Benevolent Fund.

Vacancies.

For further information refer to the advertisement columns.

Acton Hospital, Gunnersbury-lane, Acton, W.—Res. M.O. £150.
Altrincham General Hospital, Cheshire.—H.S. £125.
Belgrave Hospital for Children, Clapham-road, S.W.—Hon. Radiologist.
Birkenhead Borough Hospital.—Jun. H.S. £100.
Birmingham General Hospital.—Asst. P.
Bournemouth, Royal Victoria and West Hants Hospital.—Hon. S., Hon. Asst. M.O., Hon. Anæsth., Hon. Dermatologist, and Hon. Dent. S.'s.
Brighton, New Hospital for Women and Children.—Hon. Clin. Asst.
Brighton, Royal Alexandra Hospital for Sick Children.—H.S. £100.
Cambridge, Mental Hospital.—Med. Supt. £800.
Cardiff, Welsh National School of Medicine.—Lecturer in Pathology and Bacteriology. £750.
City of London Maternity Hospital, City-road, E.C.—Res. M.O. At rate of £100.
Douglas, Isle of Man, Noble's Hospital.—Res. H.S. £175.
East London Hospital for Children and Dispensary for Women, Shadwell, E.—Asst. P. £50.

Elizabeth Garrett Anderson Hospital, Euston-road.—H.P., Obstet. Asst., and Two H.S.'s. Each at rate of £50. Also Clin. Assts.
Evelina Hospital for Children, Southwark, S.E.—H.S. At rate of £120.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each at rate of £50.
Hove Hospital, Sackville-road.—Res. M.O. £175.
Inverness Northern Infirmary.—Jun. Med. Resident. £100.
Iraq Health Department.—Two M.O.'s. Rs.1200.
Lancashire County Council.—County Analyst. £800.
Lancaster, Borough of.—Asst. M.O.H. and Asst. Sch. M.O. £500.
Liverpool and District Heart Hospital.—Hon. P. and Asst. Hon. P.
London Hospital, Mile End, E.—Hon. Dent. Surg.
London Lock Hospital, 91, Dean-street, W.—Clinical Assistantships.
London Royal Free Hospital, School of Medicine for Women, 8, Hunter-street, W.C.—Sen. Second and Third Assts. for Obstetrical and Gynæcological Unit. £350 to £500.
Longton Hospital, Stoke-on-Trent.—H.S. £150.
Maidstone, Kent County Mental Hospital.—Asst. M.O. £300.
Maidstone, Kent County Ophthalmic Hospital.—H.S. £300.
Margate, Royal Sea Bathing Hospital.—H.S. At rate of £200.
Metropolitan Hospital, Kingsland-road, E.—Pathologist.
Miller General Hospital for South-East London, Greenwich-road, S.E.—Res. Cas. O. £150.
Northamptonshire County Council.—M.O.H. and Sch. M.O. £1100.
Norwich, City and County of.—M.O.H. £1100.
Plymouth Royal Eye Infirmary.—Hon. S.
Preston County Borough.—Asst. M.O. for Maternity and Child Welfare. £600.
Prince of Wales's General Hospital, Tottenham, N.—Clin. Assts., Hon. Anæsthetist.
Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Asst. Res. M.O. At rate of £80.
Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—H.P. At rate of £100.
Rhondda Urban District Council.—Asst. M.O. £600.
Royal College of Surgeons of England.—Examiners.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Non. Res. Cas. O. £150. Also H.S. and H.P. Each at rate of £100.
St. Bride's, Pembrokeshire, Kensington Hospital.—Asst. Res. M.O. £200.
St. Helen's County Borough.—Asst. M.O.H. £600.
Sheffield, Jessop Hospital for Women.—Asst. H.S. At rate of £100.
Singapore, College of Medicine.—Prof. of Biochemistry and Prof. of Biology. Each $850–$1000.
University of London.—Associate Examiners.
West London Hospital, Hammersmith-road, W.—H.P., H.S., Aural H.S., and Res. Cas. O. Each at rate of £100.
Willesden General Hospital, Harlesden-road, N.W.—Hon. P.

The Chief Inspector of Factories, Home Office, London, S.W., announces vacancies for Certifying Factory Surgeons at Teddington, Middlesex; Rhyl, Flintshire; Croston, Lancs; and Renfrew.

Births, Marriages, and Deaths.

BIRTHS.

BIRKETT.—On Nov. 3rd, at a nursing home, the wife of G. E. Birkett, M.C., M.R.C.S., High-street, Manchester, S.E., of a daughter.

HOLMES.—On Nov. 6th, at Denbigh, N. Wales, the wife of E. A. Holmes, M.R.C.S., of a daughter.

MARRIAGES.

BENSON—FULTON.—On Nov. 5th, at St. Paul's, Knightsbridge, Dr. Eric John Benson to Beryl Helen, youngest daughter of the late Lieut.-Colonel Carre Fulton, the Durham Light Infantry, and of Mrs. Fulton, late of Guernsey.

SHEARD—VARLEY.—Nov. 3rd, 1925, at Brock-street United Methodist Church, Lancaster, Arthur Sheard, M.D., 13, Hanover-square, Leeds, elder son of Mr. and Mrs. Joe Sheard, 36, Sunny Bank, Longwood, Huddersfield, to Alice Gertrude, eldest daughter of Mr. and Mrs. Arthur Varley, 36, Dallas-road, Lancaster.

DEATHS.

CRADDOCK.—On Nov. 4th, at "Somerdale," Greenway-lane, Bath, Samuel Craddock, M.R.C.S., aged 91.

DAVIDSON.—On Oct. 28th, at Charmouth, Dorsetshire, Harold Davidson, M.R.C.S., L.R.C.P., of Teddington, aged 64 years.

LASLETT.—On Nov. 2nd, Maurice Howard Laslett, L.R.C.P., M.R.C.S., late Captain, R.A.M.C., of Duncan-road, Gillingham, Kent.

LAY.—On Nov. 6th, at Peasenhall, Suffolk, Charles Edward Lay, M.D. Edin., L.R.C.P., M.R.C.S.

NEWTON.—On Nov. 9th, at Deene House, Kettering, Lancelot Newton, M.R.C.S., L.S.A., of Alconbury Hill, Huntingdon, aged 79.

ST. GEORGE MIVART.—On Nov. 5th, very suddenly, F. St. George Mivart, M.D., aged 70.

TODD.—On Nov. 6th, suddenly, Surg.-General Howard J. M. Todd, C.B., K.H.S., J.P., of Anglesey House, Alverstoke, aged 70.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

CONTROL OF THE FOOD-SUPPLY.

A SECOND lecture on the Control of the Food-Supply was delivered on Nov. 6th by Dr. W. J. Howarth (medical officer of health for the City of London) at the Royal Sanitary Institute, when several interesting judgments were expressed on contentious points. Dr. Howarth ranged himself on the side of those who believe that raw milk is far better than milk treated in any way by heat; he thought that dairymen who sterilise milk spoil it. All milk which has been pasteurised should be declared as such; the regulations should be varied, and it should be made an offence to treat milk without declaration. At present there is no guarantee that milk which is pasteurised quasi-secretly is not submitted to more than one treatment. Dr. Howarth held that persons had no right to engage in the milk trade unless they had the knowledge necessary to prevent their business being a danger to the public health and unless they possessed the capital necessary for its conduct on hygienic lines. The advertising caption "London's safest milk" contained a cynical suggestion; London's worst milk should make the producing cow blush. The effect of the teaching of the agricultural colleges on clean milk ought to make itself felt on the next generation of farmers.

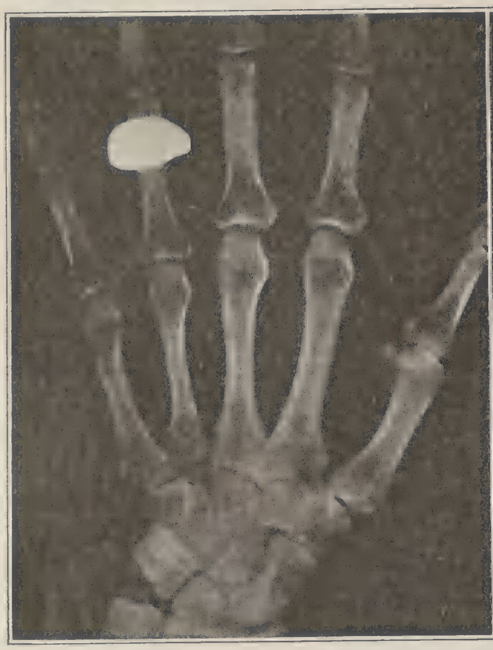
Dr. Howarth regarded the definition of cream in the Preservatives Order as "that portion of milk rich in milk fat which has been separated by skimming or otherwise" as far too indefinite. Samples of cream containing 20, 30, and 50 per cent. of fat were shown; none of them could be distinguished by the naked eye from another. On the contrary a sample of 33 per cent. homogenised cream had a richer appearance than the 50 per cent. cream, so that the public can easily be deceived and often pay the same price for articles of very different food value. A food standard of cream should be laid down by legislation. Discussing cowsheds, Dr. Howarth thought the standard in this country deplorably low, and he deplored the position reached about the legal standard of milk; case law had forced us to accept milk from the cow as a legal test of non-sophistication. If a cow gave wretchedly poor milk below the low legal standard it should be eliminated from the herd. When a farmer could send to his customer the first part of the milk drawn, which is notoriously poor in cream, and retain the second portion rich in cream for his own calves, surely we had reached the limit of statutory toleration. Some of the analyst's results which were, in a way, too satisfactory as regards fat content—fat percentages of 4, 5, or 6, or even over, being found—might be explained by the jolting of the milk churns during the long railway journey, which caused the cream to rise to the top of the milk on its arrival; it was found impossible to mix the milk so as to make the contents of the churn uniform. Milk which had been frozen presented a difficulty; the part containing the cream and the fat was the last to freeze; thawing must be gradual and the time given to subsequent mixing generous. The audience were shown two Dutch (hard) cheeses, of which the one made of skimmed milk had the better flavour, though the other was made of full cream milk. The housewife would probably buy the less nutritive. Legislation enabling the consumer to purchase according to food value was required.

The position as regards eggs was explained; no means existed for ascertaining the age of an egg within very wide limits, and legislation was contemplated which would necessitate the stamping of eggs with the name of the country of origin. Dr. Howarth thought it unreasonable to require that parcels of food containing damaged portions should be thrown away, and instanced a consignment of coffee containing unsound berries which after removal of the unsatisfactory portion had been found quite wholesome. In reply to a question he expressed the view that in spite of the results of animal experiments putrefying meat should be condemned partly on æsthetic grounds and partly because of the possible existence of more than one infection.

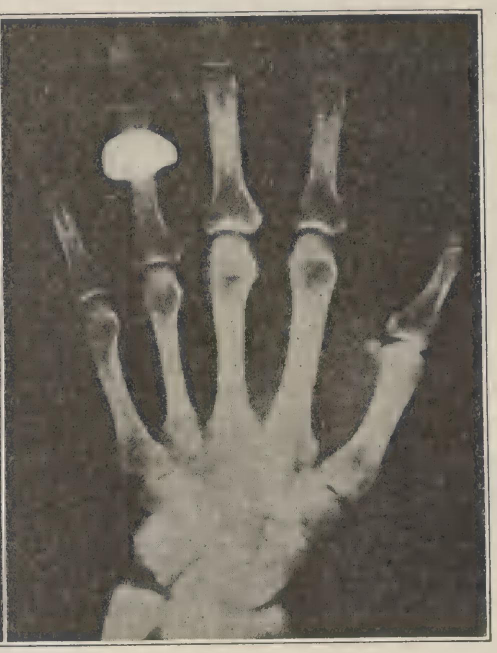
TELEPHONING RADIOGRAMS.

ON April 15th, 1925, a radiogram showing the bones of the hand was telephoned from New York to Chicago in seven minutes, and it is stated that details were not lost in transmission. We reproduce below a radiogram said to have been telephotographed and the facsimile which was received at the other end, and although there is a very definite loss of clearness, the facsimile is nevertheless remarkably accurate, and compares favourably with some reproductions of sound over the same instrument.

It is said that in sleep it is impossible to feel surprise, and the stream of modern invention is having a slightly hypnotic effect on the public. This particular invention, however, is supposed to be startling in its usefulness and especially to the medical profession. "Medical consultation between doctors on X ray plates transmitted by radio or telegraph is a realisation that should find a most useful place in these progressive times," says Dr. J. M. Steiner, radiologist to the Roosevelt Hospital, New York. "The quick transmission obtained by this method should afford untold satisfaction to both the consultant dock [sic] and the anxious family. In New York hospitals they frequently have patients who are either injured or taken ill while travelling. These patients, being in strange hands, naturally desire their home physician in consultation. If explicit information could be quickly transmitted to the home physician much needless travel could be avoided, saving the home physician or family a trip to New York. Many times physicians in other cities, desiring an opinion from a New York consultant, could materially shorten a tedious delay if X ray plates were quickly transmitted by telegraph to New York consultants, who in turn could render an opinion within an hour or two where otherwise several days to a week or more might be involved. Written descriptions or word pictures even of such simple conditions as fractures are often misleading, whereas the actual conditions shown graphically in X ray plates are more convincing."



The radiogram transmitted.



The facsimile received.

If the reproduction which the specialist is to receive were as good as the original his advice would obviously be valuable, but it is a little difficult to think of a situation in which the specialist could see more in a clouded copy than the practitioner could see in the original radiogram. The practitioner has the additional advantage of seeing the patient himself. The finer shades of structure are diminished in the photograph we have seen, and it is chiefly in the interpretation of these finer shades that the expert scores. Admittedly such a photograph might be better than "written descriptions or word pictures," and it might possibly be useful if a radiologist were present who was not also a doctor; but if the invention is to encourage the local doctor to rely on the opinion of someone who has not seen the case it should stimulate the supporters of the back-to-the-bedside movement to further activity. A story is told of a lady who received a severe fracture of the knee during a recent tornado in the Middle West and had to be taken to New York because the medical men available were not X ray specialists and could not treat her; but if the story induces reflection, it is not necessarily on the value of telephotography.

BRITISH MOSQUITOES AND THEIR BITES.

DURING recent years, and particularly since 1917, when the return of many malarious soldiers from the East gave rise to locally contracted cases of malaria in several parts of England, increased attention has been given to the annoyance and ill-health that may be caused by mosquitoes in this country. The menace of malaria ceased when sufferers from the disease no longer arrived in large numbers from abroad, but interest in the harmful activities of the mosquito in England has not abated. Cases of septicæmia following their bites are occasionally reported, and in some areas the insects are so disturbing as to discourage visitors from returning. To meet the demand for information the British Museum (Natural History) has issued a booklet on "British Mosquitoes and their Control," by F. W. Edwards, of the Department of Entomology, and Lieut.-Colonel S. P. James, M.D., of the Ministry of Health. In reference to the difficulties of control it is stated that there are 26 different species of mosquito which occur in England, and most of them have different habits of life. Some do not bite human beings; some bite mainly in houses, others in the open air; some are troublesome in spring, others in autumn; and there are differences in breeding seasons and habitat. The writers consider that it is important in any locality where anti-mosquito work is begun to make a study of the prevalent species. Measures appropriate against the adult insects and larvæ are described, and a short account of means of protection against bites. The ideal substance for the latter purpose has yet to be found, but the following preparations are suitable for general use: (1) A 50 per cent. alcoholic solution of thymol or of oil of cloves in lanolin. (2) Oil of cassia, 1 part; brown oil of camphor, 2 parts; lanolin, 4 parts. (3) Citronella oil, 1½ parts; kerosene, 1 part; coconut oil, 2 parts; to which is added carbolic acid, 1 per cent. It is useful to wear two pairs of thin stockings or socks since few mosquitoes will bite through two layers of material, however thin. An application of an alkali such as weak ammonia or washing soda will generally reduce the irritating swelling that follows a bite, and thus prevent infective scratching; in serious cases iodine in glycerine should be applied to the bite and the surrounding skin twice a day. This interesting short account of the British mosquitoes can be obtained from the Natural History Museum, Cromwell-road, S.W. 7; the price is only 6*d*.

MANCHESTER NURSES' LONG HOURS.

MANCHESTER had a "Duty Week" from Oct. 25th to 31st, when, according to posters displayed in prominent situations in the city, everyone was invited to be "on duty" in an effort to help the fund for the establishment of a new nurses' home for the Royal Infirmary. At a luncheon on Oct. 22nd Lord Derby and other speakers appealed particularly to the representatives of trades and associations for much-needed assistance. The new building alone will cost £90,000 and will consist of 270 bedrooms, sitting-rooms, and recreation-rooms. Manchester, it was pointed out, was at the moment at the bottom of large cities with regard to the hours its nurses have to work. The night staff works 73 hours a week and the day staff 63 hours. These are the bare facts and it was for them to endeavour to remedy them. For the real efficiency of the nurses more leisure was required, and in order to arrive at this by bringing the working hours down to 58 it was necessary to add 172 nurses and domestic workers to the staff of the Royal Infirmary. The Chairman of the Infirmary Board said many nurses broke down in health every year and 66 per cent. left the hospital before they had finished their first year of training. Already £36,000 had been given towards the scheme and £5000 of that was raised by the nurses themselves.

An Address

ON THE NATURE OF

MAN'S STRUCTURAL IMPERFECTIONS.

Being the Lloyd Roberts Lecture given to the Royal Society of Medicine on Nov. 16th, 1925,

BY SIR ARTHUR KEITH, F.R.S.,
CONSERVATOR OF THE MUSEUM OF THE ROYAL COLLEGE OF SURGEONS, ENGLAND.

BETWEEN the activities of Archdeacon Paley and those of Élie Metchnikoff lies the greater part of the nineteenth century. At the beginning of that century we find the Archdeacon extolling the perfections of the human body, just as Celsus had done 16 centuries before him.[1] By the close of the nineteenth century the alert and fearless brain of Élie Metchnikoff had discovered, or believed it had discovered, that the human body was blemished by many imperfections. The evangelist of this new and startling doctrine approached the study of man's body by an untrodden pathway, one made possible by the advancing science of his day. On his arrival at the Institut Pasteur in 1888, being then 43 years of age, he set himself to investigate the means by which the human body combats and keeps at bay the swarming hosts of micro-organisms which find a natural habitat in its internal passages and recesses. He saw man's body as a battlefield—the scene of a perpetual warfare—and as his investigation proceeded the conviction grew on him that the chances of the body's success were imperilled by a heritage of structures which had become out of date and useless.

In the Wild lecture, given before the Literary and Philosophical Society of Manchester on April 22nd, 1901, he declared that man "was being killed by his intestinal flora," and that his great bowel had not only become useless, but was a positive and continual menace to the rest of his body. He believed that the stomach itself, and also part of the small intestine, could be dispensed with. Early in 1903 appeared "Études sur la Nature Humaine,"[2] in which Metchnikoff greatly extended the list of man's structural imperfections.

Between the times of Paley and of Metchnikoff lie three great discoveries, and we must take note of them if we are to understand how it was possible for the one to praise the perfection of man's structure at the beginning of the nineteenth century and the other to condemn its imperfections at the end. There was first the discovery that man's body was an aggregate or society of living microscopical units; it was Metchnikoff's fortune to approach the study of man's highly complex body through the simpler societies represented by the bodies of the lower invertebrates; it was thus he came by his discovery that certain units of such societies retain their freedom, thus permitting them to serve as scavengers or phagocytes. In the second place there was Darwin's discovery; Metchnikoff was a convinced evolutionist. He therefore presumed that the alimentary outfit which served in an anthropoid phase of human evolution must be ill-adapted to deal with the dietary of civilised man. There was in the third place Pasteur's discovery, and so far as Metchnikoff's outlook was concerned this was the most potent of the three. It was under the influence of Pasteur's discoveries that Metchnikoff came to think that the destiny of man lay in the issue of the everlasting contest which went on between the living tissues of his body and the invading hosts of micro-organisms which threatened them. It is noteworthy that of the three men—Darwin, Pasteur, and Metchnikoff—who revolutionised in the nineteenth century our conception of man's body, and of the struggles to which it is subjected, not one of them was a professed anatomist; the anatomist stood too near to the subject of his study to see it in its true perspective.

Twenty-two years have come and gone since Metchnikoff's studies on "La Nature Humaine"[3] first appeared, and I propose in this lecture to ascertain how far his doctrines of man's structural imperfections and functional disharmonies has stood the test of time. His thesis presumed that Darwin's theory of man's origin was true; that presumption has been supported by every discovery of the present century, and such evidence as we now have justifies us in believing that the rate of man's evolution has been more rapid than has hitherto been supposed.[4]

THE INFLUENCE OF CIVILISATION.

We realise to-day, more precisely than was possible when Metchnikoff wrote, that the most critical chapter in man's long history opened with the discovery of agriculture, a discovery of but yesterday if we reckon time on a geological scale. Agriculture revolutionised the conditions of human life; it made modern civilisation possible. We have reason to believe that this revolution in the condition of man's life was initiated either in Mesopotamia, Egypt, or adjacent lands, not more than 8000 years ago. It is certainly not more than 5000 years ago since agriculture began to be practised in Western Europe. The vast majority of the people of these islands, probably 90 per cent. of them, are the descendants of men and women who, 200 generations ago, were dependent on the natural but precarious harvest which is provided by shore, river, forest, and moorland. City life is a new experiment for Europeans; most of us who live in London, if we could go back 20 generations, would find an ancestry which was living on the soil and of the soil. And now the poorest of us can add to our dietary produce brought from the ends of the earth. The alimentary system which was evolved to meet the needs of our primitive ancestors has now to accommodate itself to a modern dietary.

Beyond a doubt civilisation is submitting the human body to a vast and critical experiment. It is not only the alimentary system which is being subjected to new conditions; the bony and muscular framework of our bodies are being subjected to novel stresses. Of the present manhood of Britain, half earns its bread by muscular labour; the other half lives sedentary lives. Our forefathers when they arrived in Western Europe were hunters; their bodies were unaccustomed to either manual labour or an indoor life; under the stress of civilisation the hunter's body has to serve modern needs. It says much for the adaptability of the human body that it stands these stresses so well as it does. Dr. J. D. Comrie,[5] on examining 10,000 recruits for the army, found that 363 of them suffered from hernia and 113 from flat-foot. Such breakdowns in the supporting system of the body do not occur with this frequency among hunting peoples. Civilisation has laid bare some of the weak points in the human body, but the conditions which have provoked them are not of Nature's ordaining, but of man's choosing.

If modern civilisation is making new demands on our bones, muscles, and nerve controls it is otherwise with another important system of our bodies. As our manner of living increases in comfort the calls on our heat-regulating mechanism become fewer in number and less urgent in character. Our primitive forefathers lived in the open; their bodies, unhoused and scantily clad, were exposed to sun, rain, wind, and storm. Such a mode of life throws an increasing burden on the machinery which regulates body temperature—on skin, on respiratory mucous membrane, and on that elaborate system of reflexes which control the rate of internal combustion. Modern civilisation, so far as temperature is concerned, tends to make the human body a hothouse plant.

[2] An English translation, edited by Dr. P. Chalmers Mitchell, was published in 1904 under the title The Nature of Man (Heinemann).

[3] In 1907 Metchnikoff published a further work, of which an English translation appeared in the same year, edited by Dr. P. Chalmers Mitchell, under the title The Prolongation of Life. In this Metchnikoff replied to his critics and produced more evidence in support of his thesis. Sir W. Arbuthnot Lane formed the opinion that the great intestine was a useless and dangerous structure independently of Metchnikoff; so also did Prof. Barclay Smith (see an article on the Nature of the Cæcum and Appendix by the present lecturer in Brit. Med. Jour., 1912, ii., 1599).

[4] See Concerning the Rate of Man's Evolution, Nature (special supplement), August 18th, 1923.

[5] THE LANCET, 1919, ii., 959.

Failures of Adaptation.

Metchnikoff perceived that civilisation had plunged man's body into a new environment, and that the rate of its progress had far outstripped the power of adaptional response which had carried man so far beyond the anthropoid stage. A belief grew within him—almost a grudge—that Nature was letting man down. He brought against the evolutionary powers which preside over the destiny of man both sins of omission and sins of commission. We shall deal with a sample of each. The first complaint on his list of omissions is that we have not shed from our skins the last remnants of an anthropoid pelage; hair on the body, he held, was useless and a source of disease. Whether or not a completely hairless body is desirable we may leave as a moot point; a hairless breed of dogs has been produced, and, no doubt, a hairless race of man could be evolved. In this matter the Caucasian has been outstripped by the Negro and by the Mongol, the most hairless of races. It is more to the point to inquire how man has come by a comparatively hairless skin, and in the solution of this problem we have been making some advance. A hairless condition became possible with the evolution of the higher vertebrates; a fœtus in the womb draws its heat from the mother's body; it has no need of a hairy covering until the period of birth arrives. There is in the Museum of the Royal College of Surgeons of England a chimpanzee fœtus in the eighth month of development; the hair of its head and body has reached a stage identical with that of a newly born child. A stage of development which is evanescent in the fœtal anthropoid has become permanent in us. We have come by a new character through the inheritance of one evolved in fœtal life. Many of our structural features have come to us in this way.[6] The base of the human skull is greatly flexed. In the fœtal stage of all mammals the basicranial axis is bent, but in man only has this character been carried into adult years. Fœtal inheritance becomes more and more possible for man because civilisation tends to make man's world into a protective womb.

As an instance of a sin of commission, the introduction of a new and useless structure to the human body, Metchnikoff cites the case of the hymen. It is scarcely true to describe, as he does, the hymen as a new structure; it is present at a certain stage in the embryonic life of every higher mammal; it is only in the human species that it persists and forms a definite and substantial structure in the fully formed body. The hymen provides another example of the human body coming by a new character by retaining and modifying a structure which made its first appearance during embryonic or fœtal life. When we seek to explain its use, we must enter the purlieus of psychology, for round man's sense of sex has grown up a strange hinterland in his subconscious mind. Metchnikoff described the hymen as "an unpleasant impediment," but love, as the world has long recognised, thrives on impediments. The human prepuce, although not a new structure was, in Metchnikoff's opinion, a useless and dangerous one; circumcision in one generation does not diminish the completeness of its development in the next. In this the prepuce resembles the hymen. Indeed, Metchnikoff said of the latter structure that the only purpose it had ever served was "the overthrow of the dogma of the inheritance of acquired characters."

The Large Intestine.

The examples of the failure of man's body to adapt itself to present requirements which I have cited above are of little more than academic interest, but when Metchnikoff applied his analytical genius to the problems of man's alimentary system he carried us into the realms where thought becomes the guide to action. "It would be no longer rash to say (so he wrote in 1903) that not only the rudimentary appendix and the cæcum, but the whole of the human large intestine is superfluous, and that their removal would be attended with happy results." Since Metchnikoff penned this sentence the operation of complete colectomy has been performed on many thousands of men and women, but I do not think that even the surgeons who have performed this operation most frequently and most successfully would maintain that a man or woman who has been rendered colonless enjoys that moderate share of health which falls to the average intact individual. If a finger becomes permanently fixed in an awkward position the hand is improved by the amputation of the offending digit, but the relief thus gained does not restore the hand to its original capacity. The relief afforded by colectomy is of the same kind; the results of that operation in no wise bear out Metchnikoff's doctrine that the colon has become a superfluous organ in man's body. On the other hand, we have only to consult the pages of the medical press, to listen to tales which reach our ears daily, to note the ever-growing demand for patent purgatives, to be convinced that there is, as Metchnikoff maintained, a grave disharmony between the functional capacities of our great intestine and the dietary which modern civilisation has compelled us to adopt. The way out of our difficulties is not to call the colon a useless organ, a "sewage pipe," a "cesspool," but to discover its original purpose and ascertain how far we can modify our mode of living to suit its inherited capacity. What that capacity is we have yet to discover, for we have no complete or exact knowledge of the uses of the great intestine in any animal whatsoever. So far as the human organ is concerned surgery has stepped far in advance of physiology.[7]

Since Metchnikoff first promulgated his belief that the appendix, cæcum, and colon had become superfluous organs in man's body our knowledge concerning the evolution of these structures and of certain conditions which regulate their action has increased. That increase of knowledge rehabilitates the ancient belief that Nature in her evolutionary mood exercises not only a surprising ingenuity but also the strictest economy. The ferments and catalysts elaborated by plants for their own use were made to serve in the animal body as vitamins. How necessary such substances are for the proper working of the great bowel has been shown by the recent researches of McCarrison[8] and of Cramer.[9] It was for the purposes of economy that the great bowel came into existence. In fishes, the earliest vertebrate forms known to us in the living state, potent digestive juices have to be produced at the expense of body tissues; with the evolution of land-living, air-breathing forms much of this expenditure was saved by the utilisation of bacterial digestion. The great bowel was added to the original intestine for this purpose, the oldest part of this annex being the cæcum and appendix. The great bowel, as we know it in fishes, is a mere diverticulum from the hinder end of the gut; it takes no part in the digestion of food. Its epithelium forms a glandular structure which has all the appearance of an organ designed for the supply of an internal secretion.[10] That secretion, whatever it may prove to be, is carried to the liver by the inferior mesenteric vein. In the mucous membrane of the human great bowel there is set embedded in a stratum of reticular tissue—of reticulo-endothelium—some 15 millions of minute test-tube glands—the glands of Lieberkühn. No one who has noted the structure and setting of these glands and the finer changes which their cells undergo in the course of action, can believe that their sole function is to supply a lubricating fluid for the intestine; they have all the appearance of also supplying an internal secretion, and the evolutionary history of the colon favours such an inference.[11] The reticular stratum of the colon, which Dr. Scott Williamson[12] regards as the most important constituent of its mucous membrane, and in this I agree with him, represents a spleen of considerable size. Indeed, just as the liver and pancreas represent extrusions of highly specialised parts of the intestinal epithelium, the spleen represents a specialisation of the reticulo-endothelium of the alimentary canal; indeed, in Cyclostomes[13] the spleen is still intra-intestinal. Nor must we forget how closely the great intestine is linked to the central nervous system—both by afferent and efferent pathways. When we take all these considerations into account, we must conclude that the great bowel of man is not a useless or superfluous organ, but one which we, in our ignorance, are maltreating.

THE APPENDIX.

Darwin regarded the appendix as one of man's vestigial structures, and Metchnikoff accepted this verdict without demur, although there were then anatomists, particularly Prof. R. J. Berry,[14] who refused to regard the appendix as a useless structure. Every child is born with a fully and well-developed appendix, which varies in length round a mean of 35 mm. Ribbert's investigations[15] showed that amongst the Swiss the appendix has reached its maximum length, 97 mm., by the twentieth year; thereafter the average length falls slowly, so that by the sixtieth year it has become reduced to 85 mm. Prof. Berry[16] found in the population of Edinburgh that the appendix did not attain its full length, 89 mm., until the fortieth year, falling to 83 mm. by the sixtieth year. Dr. Garcia and Dr. Salloza[17] measured the length of the appendix amongst Phillipinos—a people living chiefly on a vegetarian dietary. By the twentieth year the appendix of this people had attained a length of 81 mm.; its maximum length, 96 mm., was not reached until the fiftieth year, while the average length fell to 82 mm. by the seventieth year. An organ which increases in length until the twentieth year, or even until the fiftieth, does not merit the name vestigial. The size of the appendix at birth in the various forms of anthropoid apes we do not know, but in adult gorillas, chimpanzees, and orangs the appendix usually attains a length of 150 or 160 mm.—nearly double the length of the human appendix. In the most primitive form of anthropoid known to us, the gibbon, the appendix is most variable in length. In six animals which I dissected fresh from the jungle, all of them adult, the appendix varied in length from 75 mm. to 175 mm. In two of the animals the cæcal contents were laden with numerous fruit stones as large as those of a cherry; the appendix in these two cases held a row of fruit stones, showing that it shared in the digestive work of the cæcum. There is no evidence to lead us to believe that anthropoid apes suffer from appendicitis in their natural habitat; they become subject to this disease when kept in confinement. Of 61 chimpanzees dying in captivity, ten of them suffered from appendicitis.[18] The evidence, such as it is, leads us to believe that when the appendix breaks down under the conditions of modern civilisation it does so not because it is "vestigial," but because of its inability to withstand the conditions to which it is being exposed.

To express the real nature of the structural and functional imperfections seen in the human appendix it is convenient to use a term coined by the late Sir William Gowers. He noted that in some families certain structures, such as the hair on the crown of the head, was apt to be shed as the result of a premature atrophy of the scalp. To such instances of premature senility on the part of any organ or structure he applied the term *abiotrophy*.[19] In this sense the appendix is an abiotrophic structure, one which is apt to suffer from a disordered life-history; in a large proportion of Europeans it becomes atrophic or senile when other parts of the body are in full vigour. On the evidence collected by anatomists and pathologists it is permissible to infer that if we could follow the life-histories of 1000 modern Europeans from birth to their seventieth year the following would be the fate of their appendices. By the end of the tenth year the lumen of this structure would be partially or completely obliterated in 40 of them; by the twentieth year the same fate would have overtaken 70 more; by the thirtieth year 60 others would have been added to the list; by the fortieth year 80 further cases of obliteration would have occurred; by the sixtieth year there would be 110 additional cases. Of the 1000 people who reached the age of 70, only 500 of them would retain their appendix in an unblemished functional state; in the other 500 the appendix would have undergone a premature atrophy at succeeding stages in the journey through life. In this the appendix keeps company with all structures which are of a lymphoidal nature. The tonsils, the thymus, lymphatic glands, and Peyer's patches have similar life-histories, but no one would describe them as vestiges or rudiments. There is much in the name we apply to structures; when we name them "vestigial," "congenital," or "useless" we shut the door on all further inquiry. As Paley declared a century ago, our list of "useless" structures decreases as our stock of knowledge increases.

THE EYE.

The eye, which is man's chief organ of sense has, under the stress of civilisation, become the subject of a wrong growth or abiotrophy. If we take 1000 men or women over the age of 25 we shall find that about 150 of them suffer from a degree of myopia which prevents them from seeing distant objects clearly. And yet in all of them, just as was the case of the appendix, the eye was normal at birth; the incidence of the disorder is somewhat similar to that of the appendix; it appears during the period in which the eye is undergoing growth—a process of the most complex kind[20]; in a few, myopic changes appear by the fifth year, the highest rate of incidence taking place as puberty is reached and passed. We cannot believe that among our hunting ancestors, for whom distant sight was so vital, every seventh man was myopic.

[18] Weinberg: Bull de la Soc. de Path., 1908, i., 556.

[19] Subsequently the reader will see that I use this term in a somewhat wider sense—one which includes irregular as well as reduced growth.

[20] I have dealt with the incidence and nature of myopia in Brit. Jour. of Physiological Optics, 1925, i., 369.

Myopia we must regard as a structural disharmony occasioned by the conditions which civilisation has entailed on us. Short-sight, as Dr. John Kirk has stated,[21] is certainly a disorder of growth, and the essential problem is to discover not why 15 per cent. of our population suffers from it, but why it does not occur in the remaining 85 per cent. Children may be fed on the same food and undergo the same school tasks, yet only in certain individuals does the eyeball undergo abnormal elongation. They only are affected by modern conditions, the others are not.

Perhaps no structure in the human body illustrates abiotrophic changes so well as the lens of the eye. By the age of 45 the elasticity of the lens has become so reduced in most of us that we have to seek the aid of spectacles. Some time ago Mr. Ernest Clarke[22] examined the eyes of 1200 people of all ages, and charted in graphic form the condition of the lens. From that chart we can see that some individuals at the age of 45 retain the elasticity of lens which is normal at 35 years of age, while others have reached a stage usually found in men and women of 60. It is with the lens of the eye, as with the appendix, abiotrophy sets in prematurely in some; in others the change is delayed.

THE TERM OF LIFE NATURAL TO MAN.

The consideration of the functional failure of the lens of the eye brings us to a problem which fascinated Metchnikoff. What is the term of life which is natural to man? Metchnikoff inclined to place it at 100 years—that if we escaped accident and disease the inherent vitality of our tissues was sufficient to make a centenarian of everyone—yet at the age of 45 the lens of the normal man is already old; it has reached the term of its full utility. We have no reason to suppose that civilisation has shortened or is shortening its period of usefulness. The indication it affords supports the belief that nature has worked out the evolution of the human family on a mean life tenure of 45 years; she has hitherto run the human army on a short-service system. Unfortunately we have no vital statistics of our nearest allies, the anthropoid apes. Micky, a chimpanzee which died lately in the Zoological Gardens, lived there for 26 years, and was three or four years of age when he arrived. Thirty years ago I made an intensive study on the age changes of the teeth and skulls of the great anthropoid apes, and came to the conclusion that very few of them reached the fifth decade of life. All the elastic tissue and cartilage of the body keep the lens company in their rate of ageing; they lose their resiliency by the middle of the fifth decade. The age of 45 sees the end of the term of childbearing which is normal for women. When we consult the rates of mortality which now prevail we find that a sudden rise sets in during the fifth decade, and this rise assumes a steeper and steeper gradient with every subsequent decade. All of these facts seem to show that 45 was the span allotted to man when he was the blind slave of Nature. Civilisation now permits many men and women to live the span of two such lives, but whether it would be an advantage for civilisation that all should live to be centenarians, as Metchnikoff believed, is a moot point. We must take civilisation in the round; if it has searched out the weak points in our inherited organisation it has also added incalculably to the span and comfort of life.

THE TEETH AND JAWS.

All the structural imperfections of man's body which have been discussed up to this point are of a kind which perish in the grave. We have no means of telling whether or not our remote ancestors suffered from appendicitis or were the victims of myopia. Fortunately, from this point of view there are certain of the durable parts of man's body which manifest abiotrophic changes—the teeth and jaws. During the last 20 years I have had an opportunity of examining the facial parts of over 300 individuals who lived in England more than a thousand years ago, some of them as much as eight or ten thousand years ago. Seven years ago I made an elaborate comparison between 50 of these ancient skulls, 25 of which were adjudged to be those of men and 25 of women, with equal numbers of individuals who had lived in England within the last two centuries.[23] In only three of the 50 ancient skulls did the upper and lower teeth fail to meet in an edge to edge bite; in all of the 50 modern skulls the bite was of the overlapping or scissors type. Our teeth are in an abiotrophic state; the failure of the wisdom teeth or third molars to form, or to erupt if they are formed, is but one symptom of this abiotrophic change: it affects crown, cusp, and root development. In the 50 ancient skulls, instead of 100 upper wisdom teeth, there were only 82, 13 being absent from non-development and 5 from non-eruption. In the 50 modern skulls instead of 100 upper wisdom teeth, there were only 59; 30 of these were absent from non-development, 11 from non-eruption. Such evidence shows that although abiotrophic changes had overtaken the dental system of the Western European as early as the Neolithic period, yet these changes have been accelerated during the more recent centuries. Dental abscesses were nearly as common in the ancient skulls as in the modern; carious teeth, on the other hand, were three times more frequent in modern skulls than in the ancient. The researches of the Mellanbys[24] have proved that the quality of enamel and of dentine, particularly of secondary dentine, has a relation to the vitamin content of a dietary. Equally important for the proper formation of teeth, as McCollum and his colleagues[25] have demonstrated, is the presence in food of a due proportion of certain mineral salts. Nevertheless, although a school of children are exposed equally to unfavourable conditions, it is only in a certain number that dental defects will occur; in this respect the dental system behaves as do all structures which are liable to abiotrophic changes.

In not one of the 50 ancient skulls was the palate contracted, whereas in the 50 modern skulls there were 13 in which this condition was present to a recognisable degree—in more than half of them to a marked extent. No matter which stratum of our population we make observations on, we shall find that every fourth or fifth child or adult we examine possesses a palate which, compared with the older type, may be described as both deformed in shape and reduced in size. I have never seen this defect and irregularity of palatal growth except in skulls from cemeteries of the eighteenth and nineteenth centuries. It may be thought that this irregular growth with reduction in the size of palate, and the defects in the formation of the jaws and face which usually accompany them, are merely the results of the soft and highly prepared kinds of food we eat; with such a dietary the teeth, jaws, and chewing muscles are deprived of the work which fell to them in more primitive times. That this is not the true explanation is proved by this fact. When children are fed, clothed, and exercised exactly alike all are not affected; only some of them develop irregularities of the palate and jaws. There is a special susceptibility to these imperfections in certain races and in certain families.

Amongst modern British people are to be seen various facial characters, particularly in the orbits, in the cheek bones, and in the bony supports of the nose, which are never to be noted in the facial framework of people who lived in Britain during the pre-Norman period. When a continental cartoonist seeks to represent John Bull he always emphasises these new facial characteristics. Such changes in the form of the facial bones, like contraction of the palate, which they usually accompany, are not the result of a nasal obstruction such as might be caused by enlarged adenoids or tonsils; the cause lies deeper. The incidence of irregularities in the growth of the face follow the same laws as hold for all abiotrophic structures such as the appendix, the sclerotic coat of the eye, the thymus, and the tonsil. Further research will likely prove that the disorders of growth which overtake all of these structures are linked to a disturbed action of lymphocytes and of all the constituent elements of the lymphoid tissues. Dr. W. Cramer has become convinced that lymphocytes are actively concerned in assimilation of food and in the nutrition of tissues, and that the nature of the dietary does directly affect their activities. It seems to me very probable that a fuller knowledge of the life-histories of lymphocytes, particularly of the office they perform in growing tissues, will go far to explain the disharmonies which civilisation is producing in the bodies of some of us. But the problem of explaining why some members of our community are highly susceptible to these new conditions, while others are less so, and why the majority remain unaffected, will still remain.

CONCLUSION.

I have touched only the fringe of a great subject; I have left undiscussed the numerous imperfections and disharmonies which civilisation has made manifest in structures concerned in the maintenance of posture,[26] and in those which are concerned with the circulation of blood and with the duties of respiration. I have said enough, I believe, to convince you that Metchnikoff was right when he declared that civilisation had launched man on a great experiment. From this experiment there is no turning back. We cannot return to the conditions of human life which prevailed in this country 6000 years ago; there are more people in one of the lesser back streets of London than could find an existence in the whole length and breadth of the Thames valley if we returned to the manner of living of our distant ancestors. We cannot go back; we must go on. Seeing how differently we are now circumstanced in every relationship of life—in food, in drink, in shelter, in warmth, in occupation, and in amusement—the wonder is, not that structural imperfections and functional disharmonies should develop in a proportion of our numbers, but that so many of us should escape harm altogether and enjoy good health. It says much for the adaptational reaction which is inherent to the human body that it withstands the artificial conditions of modern civilisation as well as it does.

How are our bodies to be protected against these ills with which civilisation threatens them? Metchnikoff, a declared and open rebel against Nature, hoped that science might discover some short cut for man's escape, some way of speeding up the evolutionary machinery of his body, and so making it perfectly fitted for the life which ever-advancing civilisation is forcing on mankind. I also believe that science will find a means of escape, but not by Metchnikoff's way. The solution of our problem is a fuller knowledge of the use and working of those parts of our bodies which are most apt to give way under our modern ways of living—the use of such structures as the great bowel. And when we have replaced our ignorance by real knowledge we shall then be in a position, not to adapt our bodily structures to our mode of living, but our mode of living to our bodily structures. This seems to me the best way out.

---

An Address

ON THE PROPHYLAXIS OF THE COMMON COLD AND FEBRILE CATARRHS.

Delivered before the Medical Officers of Schools Association on Nov. 6th, 1925,

BY A. I. SIMEY, M.D. CAMB., F.R.C.P. LOND.,
MEDICAL OFFICER, RUGBY SCHOOL.

IN this paper I use the terms "common cold" and "febrile catarrhs" to indicate all those affections of the respiratory passages ranging from the common cold or coryza, on the one hand, to the diseases known variously as febricula, "flu," P.U.O., "chill," and "influenza" on the other hand, which, however much they differ in their manifestations, have this in common, that they are all infections, and all *begin* in the upper respiratory passages, causing malaise, often pyrexia, and a set-back in the normal healthy progress of adolescence. I intend, also, to deal with the prevention of these diseases *in schools*, especially the boarding schools, in which infection is so much more likely to spread, because the pupils feed, work, and sleep in common dining-halls, studies, class-rooms, and dormitories. Moreover, it is in these schools that great difficulty is experienced in finding adequate sanatorium accommodation for the patients, who so often require skilled nursing and attention in large numbers at the same time. I shall also use the term "influenza" loosely to cover all those febrile manifestations to which I have already alluded.

The appearance of these diseases in epidemic form is a matter of very great importance to schools for two main reasons: 1. Because, even though they run a normal uncomplicated course, they interfere with the work of the individual, whilst if complications arise they may jeopardise his future health and even his life. 2. Because they disorganise the whole life of the school, and are most expensive both as regards time and money. The work of a school medical officer would be reduced by one-half at least if such epidemics could be eliminated.

It would appear logical to begin by a description of the various forms of the disease as met with by medical officers of schools, and the different types which it assumes in different epidemics—e.g., the catarrhal, the anginoid, the intestinal type, and so forth. But I take it that all of us know it, with all its protean manifestations, and that we are agreed that the phenomena of this disease are due to micro-organisms, and that they are acutely infectious. The question as to the particular organisms concerned has not been finally settled, but we know that when cultures are made from the sputum or mucus of affected patients a variety of organisms are usually isolated which, if not the prime or deciding cause, are, at any rate, aiders and abettors or accomplices of the arch-offender, who or whatever he may be. Their entry into the body is by the upper respiratory passages. As to predisposing causes we can say little. It is well known that the vigorous and healthy are attacked almost as readily as those who have a less healthy constitution, though deformities of the nasal septum and turbinate bones, and the presence of unhealthy adenoid and tonsillar tissues no doubt weigh to some extent in the balance.

PREDISPOSING CAUSES.

What we know about predisposing causes is very little, and the prevention of the disease depends largely on the degree of immunity in any community for the time being. I do not mean to say that it counts for nothing if a child sits in a draught, or goes about in wet clothes or imperfectly clad, for these conditions temporarily depress vitality, but in the majority of our patients we cannot, as a rule, lay much stress on any of those conditions as a contributing cause.

Some blame the inclemency of the weather, and lay stress on seasonal incidence; others point out a certain periodicity in the waves of visitation; but whilst there may be some ground for both of these suggestions, the probability is that we can say little more than that the bodies of mankind have been discovered to be a first-rate culture medium by certain bacteria, which go on increasing in numbers and in virulence until the soil is temporarily exhausted or otherwise made untenable for their activities.

No doubt climate and season are a small factor in their environment which influence the outbreak and decline of epidemics, but it is more likely that the bacteria are themselves the victims of their own activity, and require either fresh feeding-ground or a rotation of bacterial crops before they can thrive again in the same host.

ATTEMPTS AT LOCAL ANTISEPSIS.

Attempts have been made to make the human soil untenable by disinfecting the upper respiratory passages by means of sprays, gargles, nasal douches, &c. But there are two considerations which, to my mind, make it most improbable that these measures can be of any avail.

1. The disinfectants used, if strong enough to kill the germs, will damage the epithelium with which our throats and nostrils are provided to deal with infection.

2. Even if strong enough, their contact with the micro-organisms is so short (for they are soon washed away or diluted) that the protection is likely to last for a question of minutes only. In this connexion I have noticed that where there is much nasal catarrh, constitutional symptoms do not develop so often or so severely. For by the catarrh Nature fixes and localises the disease to the naso-pharynx and "deals with it," so to speak, in situ. A common history to obtain at the outset of an attack of influenza is that the patient has recently had an ordinary cold for some time without feeling ill, but when the catarrh ceased constitutional symptoms with malaise and pyrexia first appeared. A remedy for colds much in use at one time was the "carbolic smoke-ball." Its virtue, no doubt, consisted, not in the antiseptic power of the carbolic acid, but in the fact that it produced an aseptic irritation of the nasal mucosa and caused an excess of mucus to be formed which dealt with the invading infection there and then.

With the same object in view, some medical officers have tried to educate their pupils to breathe habitually and entirely through their noses by teaching them a kind of "nasal drill." This expedient is difficult to carry out effectively and has not met with signal success: it has psychical rather than physical results.

Again, it has been suggested that all pupils should have their throats and nasal passages disinfected periodically by passing through a chamber in which a saturated spray of some vaporised disinfectant is circulated. I think this measure also is open to the criticism that the effect is too temporary and superficial to be efficacious.

PRINCIPLES OF PROPHYLAXIS.

The prophylaxis of these diseases then resolves itself into the following rules: 1. Keep out of infection's way. 2. Raise the immunity of the body. Let us deal with these separately.

1. *Avoidance of Infection.*—How can school-children keep out of infection's way? This is a large and far-reaching question. The infection is usually brought into schools at the beginning of a term by boys or girls who have left home with a cold or cough which seemed too trivial to detain them, or who during the last week of the holidays have gone through a concentrated tour of amusements at kinemas, theatres, dances, &c., and return to school somewhat tired and out of sorts, with the diseases under question incubating in their systems.

The way to tackle this source of infection is to "educate" the parents, or rather take them into our confidence, and point out the folly of indulgence of this kind. I have found it of no avail to send out a printed form, such as: "You are requested not to send your boy back to school with a heavy cold." To be of any use, a special communication must be sent periodically, written in reasonable terms, with explanations, and an appeal for coöperation on the part of the parents. Moreover, in schools situated in or near a town there is a constant risk of the infection being introduced by day-boys or boarders who must needs enter shops, hotels, and other town buildings to replenish their wardrobes, meet their parents, or go to theatrical or musical entertainments. This is to a certain extent avoided by stringent rules as to bounds and hours, and by providing the school with a food-shop of its own; but, inasmuch as the strength of a chain is that of its weakest link, all such efforts at surveillance and restrictions must almost inevitably break down, as it is enough that one pupil introduce the infection for the whole school to be exposed to its attack.

But if we ask for preliminary care on the part of parents we, too, must leave no stone unturned to avoid infection when the pupils assemble at the beginning of each term. Precautions should be taken by school authorities to ensure that all school premises are in as suitable condition as possible for pupils who have come from comfortable home-quarters to the severer rigour of the school establishments. In addition to the thorough routine cleaning and ventilation of school premises, all class-rooms and other meeting places should be warmed by the lighting of fires a few days before the pupils return, and the school routine should be entered upon gradually, not plunging at once into early hours, but gradually training the pupils to adapt themselves to their change of environment. No doubt, colds and febrile catarrhs spread much more quickly amongst boys and girls when living in their school community because they are packed into close quarters both by day and night.

It is, in my experience, chiefly in the big dormitory and small study where two or more boys live and work together that infection most easily spreads. Stated in other terms this means that they are overcrowded, and no doubt in a sense they are so, but it would be neither possible nor desirable to house boys at school as young men live at the universities—i.e., each with his own sitting-room and bedroom quite apart from that of his neighbours. Such an arrangement would materially alter the value of our boarding-schools in which close contact and publicity of life are important social and moral factors. I am quite sure that, even in dormitories where ample space (according to the accepted doctrines) is allowed, infection is carried directly from boy to boy.

There are only two remedies for these difficulties:—

(*a*) To rebuild or rearrange existing accommodation so that there are far fewer boys in each dormitory, after the plan adopted in some fever hospitals, where separate infections are nursed in the same ward without obvious ill-effects. But so long as boys are boys the theory would utterly break down in practice. There is all the difference in the world between sick patients in bed in a ward under supervision and healthy children in a dormitory with little or modified restraint. But this does not mean that we should not be strict as to the spacing of beds and ventilation in dormitories. On the contrary, the minimum space provided should at least be in accordance with the usually accepted rules, and great care should be taken that the ventilation is as good as possible.

(*b*) To make the best use of what space is available in studies and dormitories. Here, I think, a great deal could be done if more attention were paid to tidiness both of place and person. In my opinion, pupils should be paraded every morning to see that they begin the day, at any rate, tidy in appearance and apparel, and their quarters should likewise be inspected daily by a specially selected master or officer to see that they are kept clean and well ventilated. This is especially necessary where boys live and sleep in the same room, and every attempt should be made to keep such rooms free from unnecessary furniture, draperies, and other dust-collecting materials. The condition of class-rooms and other meeting places likewise requires special attention to see that they are kept clean, warm, well ventilated, and adequately lighted.

In the holidays following an epidemic, special care should be taken to begin cleaning and decorating operations *early*. I do not think that the burning of sulphur or formalin, as usually employed, has any germicidal action whatsoever, and I regard it as an unnecessary performance in which far too much trust is placed by the public and ourselves.

My impression is that girls' schools suffer less from influenzoid epidemics than boys' schools of the same grade. If this is so, I have little doubt that it is due to the greater care spent upon tidiness and general supervision of living quarters rather than to their being less closely packed. I feel sure that 100 tidy pupils will occupy the same space as 80 untidy pupils without a corresponding increase in the incidence of febrile complaints. There are many other small but important considerations which I must pass over, such as the kind and amount of food, the laundry arrangements, the hours of sleep, &c., which bear indirectly on our subject.

But there is one small detail to which insufficient attention is usually given in schools, and that is the provision of adequate foot-gear. I cannot explain why cold and damp feet should predispose to catarrhal conditions any more than coldness and dampness of any other part of the body, except that it is more often overlooked. One of the inconveniences of adolescence is a tendency to poor circulation in the extremities, and this can to a certain extent be overcome by seeing that pupils are well shod and that their boots and shoes are kept in good repair.

2. *Raising the Immunity.*—There are some individuals who seem to have a high natural immunity to infections of all kinds; some children, even before puberty, will pass through epidemics of different kinds unscathed, and it is possible that, with puberty, most people acquire a still greater degree of natural immunity. A second class, possessing less natural immunity, suffer from occasional attacks of influenza, but acquire after each attack an immunity which lasts them for a considerable length of time. There remain, however, a large number of persons of school age who acquire only a very short-lived immunity after an attack of influenza, and succumb whenever the so-called "wave" passes over their neighbourhood.

In a school of 600 boys I have known 200 to be on the sick list at one time, and a total of over 300 cases in a term, which implies the loss of about 4000 school days in a term of 12 weeks.

PROPHYLACTIC VACCINATION.

It seems to me that the longer the epidemic lasts the greater is the virulence of the infection and the more serious the nature of the complications. Consequently, it behoves us as medical officers to leave no stone unturned, at whatever cost or trouble, to stamp out or mitigate the disease and its sequelæ, and I would like to direct attention to the question of raising the immunity of the community by prophylactic vaccination.

There has so far been no combined attempt on the part of medical officers of schools to tackle a given epidemic systematically by methods and on lines on which they have previously arrived at agreement. At present the question is in a state of chaos, and I do not think that we could arrive at any certain conclusions if we had before us to-day all such evidence as can be collected, because of its fragmentary and uncoördinated nature.

There is on the one hand: 1. The evidence of individual patients who think they have or have not benefited by a "course" of prophylactic vaccines, and who swear by or belittle this form of vaccination according to the result they imagine it has produced in themselves. 2. There is the evidence of medical men who have dealt with communities such as a detachment of troops, schools, and other societies, whose evidence, if we were able to collect it, would in some cases be enthusiastic, in others lukewarm, but in no case convincing, because the methods have not been carried out on a large enough scale and with sufficient control material.

What is wanted is a combined test-effort on the part of medical officers of schools to tackle the problem thoroughly by agreeing as to the method of preparation and details of administering a vaccine at a time chosen by the doctors calculated to immunise pupils against a likely, or one may say, almost certain outbreak of influenzoid epidemic at a given season—e.g., the coming Lent term.

It may be argued that as the organism responsible for influenza is not certainly identified, this form of prophylactic vaccination is unscientific, but we do certainly know that certain accessory organisms play a not unimportant part both in the disease as we know it and in its complications. Indeed, there may possibly be no one particular responsible germ, but the disease may be due to the combined activity of several organisms, some of which we know—for instance, the virulent form of streptococcus so frequently isolated from otorrhœa following influenza. If, then, we can raise the immunity of the body against one or more such organisms we are immunising in part or in whole against the complex disease.

Stock Vaccine.—There has lately appeared in print a report of an experiment tried in September, 1919, in a boarding-house of a large public school, where each child received five injections in the course of the year of the anticatarrh vaccine made in the inoculation department of St. Mary's Hospital. The report says: "The results were so encouraging that the procedure has been continued regularly, and the record for the past four years shows that not one girl who had been duly inoculated missed a single day at school owing to colds or influenza, whereas of those girls who were not inoculated a considerable number were confined to bed with colds and influenza, and two contracted pneumonia." In this house the number of girls averaged 40, and they mixed freely with other uninoculated pupils in their class-rooms.

The vaccine here used is composed of *Micrococcus catarrhalis*, *Bacillus pneumoniæ*, pneumococcus, *Bacillus septus*, *Bacillus influenzæ*, and streptococcus in certain definite proportions, and is, no doubt, constantly reinforced at headquarters by fresh cultures taken from well-marked cases of the disease. The recorded results are excellent, but I would suggest that it would be still better if those schools which determined to join in one big concerted experiment should send to a prearranged laboratory or pathologist cultures from the naso-pharynx and throat and specimens of sputum by a given date, in order to have a vaccine of local origin made for them, leaving it to the discretion of the pathologist to incorporate such and as many strains as his experience led him to think necessary.

Such a vaccine would combine the advantages of being easily procurable and of being made from local material. This concerted experiment would have two sources of control: 1. Those schools which, for some reason, did not adopt the plan. 2. Those individuals in any school whose parents preferred not to have their children inoculated. The best time for administering the vaccine would be during the Christmas holidays immediately preceding the Lent term, and again during the last three weeks of the summer holidays so as to precede the two school winter terms in which influenza is usually most prevalent.

I feel that we have before us a great opportunity for testing the efficacy of vaccine prophylactic treatment in the case of a disease which has become a national danger and expense, and that the time has come to give it a careful trial. I often feel and say that the value of my work as medical officer of a big public school can only be judged when the boys whom I have steered through adolescence reach the fourth and fifth decade of their life. The proof of this pudding is not in the eating but in the digesting. The success of education at our schools cannot be judged by lists of scholastic distinctions so much as by the mentality and usefulness of their pupils when they attain middle age. The same, I take it, is true in medical matters, and we medical officers of schools hold in our hands the invisible keys which could open many secrets of the future health of our patients.

SENSIBILITY OF THE HEART: A HUMAN EXPERIMENT.

BY GEORGE WAUGH, F.R.C.S. ENG.,
SENIOR SURGEON, HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET, AND HAMPSTEAD GENERAL HOSPITAL.

With Notes by

SIR WILLIAM WILLCOX, K.C.I.E., M.D. LOND.,
PHYSICIAN, ST. MARY'S HOSPITAL, ETC.;

AND

FELIX ROOD, M.B., B.S. DURH.,
HON. ANÆSTHETIST, UNIVERSITY COLLEGE HOSPITAL.

THE opportunity for a comparatively prolonged manipulation of the human heart in a fully conscious patient has occurred probably with sufficient infrequency to justify placing on record this case. As nearly five years have now elapsed since the date of the operation it is possible to add that the health of the patient is excellent and fully warranted the risk that was taken in exposing him to an experimental procedure. At the time of the operation his condition was one of extreme gravity and apparently hopeless. For obvious reasons, that will be explained later, a general anæsthetic could not be administered. The use of an appropriately planned regional analgesia for making a flap from the wall of the thorax was not an entire innovation, but there was no precedent to guide us as to the sensitiveness of the visceral pericardium and heart to such stimuli that the tearing down of adhesions, squeezing, and ordinary tactile pressure might evoke. Operations upon the heart had been done long previously to the discovery of general anæsthetics, and an excellent résumé of the history of cardiac surgery from early days is given by Ballance in his book "The Surgery of the Heart." But, as a rule, these operations were for severe wounds from which the patients were barely conscious and were hurried procedures that were necessitated by such emergencies. Dobson,[1] in April, 1924, successfully sutured a wound in the heart under "local anæsthesia." Another type of operation was for suppuration within the pericardium when simple incisions were made to establish drainage. In this particular case an exploratory pericardiotomy was carried out with a purely regional and local analgesia in the hope of discovering a lesion that could be benefited by surgical treatment upon a patient who was so normally conscious that he has forgotten none of the details of his experiences throughout the operation at the present day. The lesion found was a fibroplastic pericarditis binding tightly the whole of the heart muscle to the parietal pericardium with small lacunar spaces containing serous fluid intervening at intervals. The length of time taken to free the whole of the heart from its attachment to the pericardium was from 10 to 12 minutes, and the whole operation occupied about 35 minutes. At no stage of the operation did any stimulus that was applied produce any sensation that the patient was able to record in consciousness, and throughout most of the proceedings he chatted with his nurse. Neither is this the sequence of amnesia, as he can relate fully all the ordinary details of the operation that he observed at the present day.

Lennander (Upsala) and A. E. Barker (London) showed 25 years ago by operations upon the conscious human subject with local infiltration of the abdominal wall only that the alimentary tract deriving its nerve-supply from the vagus and sympathetic nervous systems was totally insensitive to all forms of stimuli except traction. The visceral layer of the pericardium and the heart in the human being deriving their nerve-supply from the same sources are shown by this operation to possess the same immunity to the stimuli applied in this case. It was further noted during the whole time when the heart was being manipulated that its beat was entirely unaffected in any way that could be recognised by the hand of the surgeon, an observation naturally of great relief to the operator. There was no subsequent reaction when the operation had been completed; actually the patient had 12 hours natural sleep immediately afterwards and the pulse-rate fell within the same period from 148 to 130 beats per minute. Such knowledge may extend conceivably the sphere of utility of cardiac surgery.

The pathological condition that was revealed at the operation fully explained the absence of any pathognomonic clinical signs for detecting its presence, as well as a reason for the cardiac shadow, examined beforehand on two occasions by X rays, showing little or no variation from the normal. The parietal pericardium, which was fully a quarter of an inch thick, clamped the heart like the case of an oncometer, and thus rendered the occurrence of enlargement or displacement impossible. This condition has been found not infrequently in the post-mortem room in cases of acute pulmonary disease as a lesion, the presence of which had not been detected beforehand. It is possible that the lives of some of those patients might have been saved by the procedure adopted in this case, which enabled a systematic and painless investigation of the pericardial contents to be carried out without the added risk of a general anæsthetic to a patient already desperately ill.

The purely medical aspects and clinical difficulties of this case were under the supervision of Sir William Willcox. I must express my thanks to him, to Dr. E. F. Furber, and to Dr. G. P. Selby (the father of the patient) for their unwearying skill and assistance in helping towards a successful termination; and not least to Dr. F. Rood for an induction of analgesia that by its perfection gave courage and confidence throughout an anxious procedure.

Details of Case.

C. P. S., aged 21 years, an officer in the R.F.C., was sent to me on Dec. 2nd, 1920, suffering from an intractable neuralgia of the median and ulnar nerves and an axial causalgia of the phantom limb of a high amputation of the left arm. He had been shot down when flying behind the German lines, and in addition to many injuries a virulent spreading sepsis of a compound fracture in the region of the left elbow-joint ultimately necessitated amputation. Ten days later a violent secondary hæmorrhage had been arrested by an urgent application of a mass ligature to the bleeding-point as he was lying in bed almost dead. (It is pleasing to put on record that he received every possible attention at the hands of the German medical service, and when the surgeon in charge o the hospital learned that the patient's father was a medical man he took the trouble to write a full technica account of the progress of the case on the back o each letter that the patient was permitted to writ home.) The symptoms suggested that the median and ulnar nerves had been included in this ligatur as well as the blood-vessels. But the causalgia wa by far the more formidable sequela, and during it agonising spasms clonic convulsions of the shoulde girdle muscles occurred as well as pink macula areas of vaso-dilatation over the same region.

At the first operation on Dec. 15th, 1920, th median and ulnar nerves and the brachial vessel were found to end in a cone-shaped terminatio distal to which the nerves expanded into larg fibro-neuromatous masses. These were resected and the ends of the nerves infolded. The sheaths of the vessels were then cleaned high up as far as the second part of the axillary artery (Leriche's operation). The region traversed in order to identify all these structures was a dense oozing fibrous mass, and the patient was exposed to the influence of open ether for nearly two hours. His temperature rose within 24 hours of the operation to 104° F., and a few days later Sir William Willcox and Dr. Furber diagnosed an extensive pneumonia of the right lung. By Dec. 23rd, 1920, a large pleural effusion had developed and two pints of a blood-stained serous fluid were drawn off by aspiration. Cultures from the fluid produced a pure growth of a hæmolytic streptococcus. A few days later an intercostal incision was made under local analgesia and Carrel-Dakin tubes inserted into what was by then an empyema cavity.

---

[1] Dobson: Brit. Med. Jour., 1924,

On Jan. 2nd, 1921, patient complained of præcordial pain, and after examination Sir William Willcox diagnosed the presence of acute pericarditis. By Jan. 5th the pain had disappeared, but the patient remained acutely ill with a temperature of 103·4° F. and pulse-rate 132. On the 9th a rib was resected on the right side, again under local analgesia, as the drainage through the intercostal incision was not proving satisfactory. An abundant purulent discharge ensued from the empyema, which was still being treated by the Carrel-Dakin method, and an improvement in the general condition of the patient was maintained until Jan. 15th. From this date, however, in spite of a marked improvement in the condition of the empyema, the general condition of the patient became steadily worse. The temperature seldom fell below 102°, and the pulse-rate climbed up from an average 120–130 to an average 130–144. On Jan. 23rd the pulse-rate reached 148; the condition of the patient was then very grave, and after a consultation with Sir William Willcox, Dr. J. F. Poynton, Dr. Furber, and the patient's father a decision was arrived at to explore the pericardial cavity by operation, since the condition of the empyema was not sufficient to explain the critical condition of the patient.

Operation (6 P.M., Jan. 23rd, 1921).—After a preliminary injection of novocaine by Dr. F. Rood (for details of the procedure see note by Dr. Rood), a U-shaped incision was made over the left side of the chest so as to expose the sternal ends of the third, fourth, and fifth costal cartilages. These were cut through obliquely close to the sternum and a chrondro-plastic flap was then turned outwards using the costochondral articulations as hinges. The edges of the pleural sacs were easily identified and painlessly brushed aside with gauze. The pericardial sac was then steadied by transfixion with a sharp hook and an incision ¾ inch long was made cautiously through its thickened substance. At a depth of rather more than ¼ inch a small cavity was opened, from which about 2 drachms of turbid fluid escaped. The floor of the cavity was formed by the heart muscle and its other boundaries by recent fibrous adhesions. These were broken down carefully by the finger all round and similar small cavities opened beyond them. As the pathological condition within the pericardial sac was now obvious, the original incision in the parietal pericardium was extended upwards and downwards for about 5 inches to give access to the whole of the heart. By means of blunt instruments and fingers introduced into the sac the whole of the heart muscle was freed eventually from its attachment to the pericardium. The most difficult part was the upper portion of the posterior surface, which could be reached only after the apex, anterior surface, and lateral borders of the heart had been liberated. To effect the final step, the heart was grasped between the thumb in front and the middle and index-fingers behind. With the hand thus steadied the fingers behind were forced slowly up to the apex of the pericardial sac and with sweeping movements completed the destruction of the last of the adhesions. At no time did any detectable change in rate or quality of the heart-beat occur suggestive of resentment of these manœuvres, and the patient, as before, continued to remain quite unaware of any unpleasant proceeding. The condition of the patient was so excellent and his repeated reassurances that he felt nothing enabled the rest of the operation, involving the replacement of the chondro-plastic flap, to be conducted in a routine and orderly manner. A small piece of the fifth chondral cartilage was removed (he heard the noise made by cutting through this) to enable a drainage-tube to be placed in the pericardial sac, and the remaining cartilages were stitched back to their sternal attachments by chromic catgut. At one stage of the operation the patient said that he thought that something warm was trickling over his chest, but otherwise he experienced no sensations that gave him any knowledge of anything being done to him. He chatted frequently with the nurse standing by him, and has a clear recollection at the present day of the whole incident.

After-course.—Cultures from the pericardial fluid proved to be sterile, but a free discharge of it occurred for several days and the tube was only finally removed a fortnight after the operation. His general condition improved immediately and progressively after the operation, but a tedious convalescence was interrupted by a pulmonary infarct on Feb. 3rd, and by a premature closing of the empyema wound on Feb. 28th, which necessitated a temporary reopening. He became finally non-febrile on March 1st, and from that time onwards his pulse-rate only rose at intervals to 96. On May 7th, 1921, he was able to travel a distance of 40 miles by motor car to the country, with a pulse-rate that varied from 72 to 80. During the ensuing years he has led an active athletic life—e.g., running with harriers, swimming, sailing his own boat, playing tennis, and punting a heavily laden punt a distance of six miles or more without fatigue. Incidentally, in the midst of all these infections, the operation wound on his stump healed by first intention and he has remained free from both neuralgia and causalgia.

Note by Dr. F. ROOD.

About 5 oz. of a 2 per cent. solution of novocaine were used to produce analgesia in this case—20 ♏ of adrenalin were added to the novocaine solution in order to localise it to the site of injection and thus to prolong its action. As the operation involved exploration of the pericardium, it was, of course, necessary to produce an analgesia of the whole thickness of the chest wall and over a sufficiently wide area to allow not only for the line of incision, but also for retraction and other manipulations associated with the operation.

Thus it was necessary to render insensitive first the skin and subcutaneous tissues, then the deeper layer—the ribs, costal cartilages, and parietal pleura; finally, the *parietal* pericardium. It was naturally not possible to inject the nerves supplying the *visceral* pericardium and the heart, so that the manipulation of these tissues was the only part of the operation which could not be definitely provided for in the analgesia. This part of the operation was somewhat experimental, as we did not know previously to what extent the conscious patient would tolerate operative procedure in the interior of the pericardium.

As the skin and subcutaneous tissues over the præcordium are supplied in the upper part by the third and fourth descending branches of the cervical plexus as well as by the terminal branches of the intercostal nerves and also by the lateral cutaneous branches of these same nerves, a wide infiltration with a very fine hypodermic needle was carried out over an area of the chest wall extending from the junction of the manubrium and body of the sternum above to the ensiform cartilage below, and reaching laterally for about 3 inches on either side of the sternum. Then injecting through this insensitive area with a longer and stouter needle, the novocaine solution was introduced beneath each separate rib and costal cartilage. As this second layer of injection blocked the trunks of the intercostal nerves it produced a complete anæsthesia at the ribs and costal cartilages, the intercostal muscles, the parietal pleura, and the parietal pericardium.

This tedious infiltration method was employed rather than a pure regional anæsthesia of each intercostal nerve beneath the ribs, as the latter would have involved a series of painful punctures which, in view of the patient's condition, was not considered advisable. The patient stood the operation very well. There was no alteration in his general condition at any time and he did not resent in the least gentle intrapericardial exploration.

Note by Sir WILLIAM WILLCOX.

The usual signs of an extensive pneumonia of the lower lobe of the right lung were present on Dec. 17th, 1920, the temperature ranged from 105° to 103° F., and rusty sputum of the usual pneumonia character was freely expectorated. On Dec. 23rd, 1920, 11 A.M., the temperature still remained high, and after careful examination and consultation with Dr. E. P. Furber, whose care and attendance on the case were constant and unremitting, it became evident that fluid was present in the right pleural cavity. 10 c.cm. of slightly turbid fluid were withdrawn with an aspirating needle, and on examination by Dr. John Matthews streptococci of hæmolytic type was found to be present. On Dec. 23rd two pints of blood-stained serous fluid were aspirated by Mr. Waugh, and treatment of the right pleural cavity by Carrel-Dakin tubes was instituted. On Dec. 28th, 1920, pain occurred over the præcordial region and definite pericardial friction was detected. The temperature remained high and a well-marked pericardial rub continued audible over the præcordial region. There were still well-marked signs of fluid in the right pleural cavity, the discharge from which was of a thick purulent nature, but the præcordial pain disappeared on Jan. 5th.

On Jan. 9th, 1921, a portion of rib was resected by Mr. Waugh and a large drainage-tube inserted into the right pleural cavity. In spite of the adequate drainage of the empyema cavity the temperature remained high and a rapid pulse-rate and dyspnœa persisted with the condition of the patient growing steadily worse. It appeared clear, on clinical grounds, that the urgent symptoms could not be explained by the condition of the right pleural cavity, there being no physical signs of any collection of pus.

On Jan. 22nd, 1921, a careful X ray examination of the chest showed the right pleural cavity to be well drained and some slight increase in the cardiac shadow. The condition of the patient was so extremely grave, and it was obvious that unless surgical measures were invoked for the treatment of the pericardial condition a fatal termination would certainly follow speedily.

When on the morning of Jan. 23rd, 1921, the condition showed no improvement a final consultation was held, and Dr. F. J. Poynton very kindly saw the patient with us and reviewed the whole situation. It was unanimously agreed that operation on the pericardium for relief of the acute fibrino-plastic pericarditis held out the only possible hope of recovery. The operation was performed on that day and its details have been most accurately described by Mr. Waugh. It was my privilege to be present and observe the whole procedure. Before the operation the pulse-rate was 148, the temperature 104°, and the condition of the patient could only be described as desperate. The skill with which the local anæsthesia was carried out by Dr. Rood completely obviated the slightest pain or shock from the operation. The operation was performed with the utmost skill and rapidity, the heart being exposed and freed from its strangulating fibrino-plastic adhesions, turbid fluid escaping from the pericardial cavity, which was freely drained.

A most interesting feature of the case was that while the right pleural cavity was heavily infected with hæmolytic streptococci, and had obviously given rise to the pericarditis, yet the turbid pericardial fluid was completely sterile. This is a perfect illustration of the manner in which a septic focus caused by a definite bacterial infection may give rise to a very marked inflammatory reaction in another part of the body, the latter showing a complete absence of living bacteria.

In this case it appears probable that streptococci had been conveyed to the pericardium from the right-sided empyema, and that they had been completely destroyed by the bactericidal action of the pericardial fluid, their products, however, giving rise to the active inflammation—i.e., fibrino-plastic pericarditis. The occurrence of arthritis and very many other pathological inflammatory lesions of a sterile nature resulting from a distant focus of active bacterial infection can be accounted for on similar grounds.

The operative procedure employed in this case appears to open up a new field for the treatment of pericardial disease. The exposure of the præcordium and the opening of the pericardium are attended with little or no shock under the technique employed, and the freeing of the heart from pericardial adhesions, if newly formed, as in this case, is within the realms of practical surgery.

OBSERVATIONS UPON THE INFLUENCE OF A GLYCERINE EMULSION OF TESTES AND ADRENALS

ON TUBERCULOUS AND SENILE PATIENTS.

By V. KORENCHEVSKY, M.D.

(From the Lister Institute of Preventive Medicine.)

Historical.

1. *Adrenals.*—Several authors have a strong opinion that the functional capacity of the adrenals is important in infectious diseases, increasing or decreasing the resistance of the organism to disease (Poncet and R. Lerische (1912), M. Lucien and Parisot (1913), Biedl (1916), Cramer (1919), Lewis (1921–23), Scott (1924), and others). The action of bacterial toxins upon the adrenals seems to vary according to the degree of their toxicity and the period of time during which the animal organism is subjected to their influence. Tscheboksaroff (1911) found that during the first 10–15 hours after the injection of diphtheria toxin the amount of adrenalin in the blood is increased and in 24–27 hours following the end of this period is again normal; 2–4 days after the injection the secretion of adrenalin has decreased or ceased. Experimental data, corroborated by anatomical investigations of the adrenals of patients who died of infectious diseases, showed morphological changes in these glands varying from hyperæmia and hypertrophy to degeneration and atrophy, according to the time and strength of action of the toxins (Langois and Charrin (1896), Bogomoletz (1905), Goldzieher (1910), Lucksh (1910), Sorgo and Haletin (1916), Cramer (1919) and others). The suprarenals were investigated and found to be affected in tuberculosis (Bernard and Bigart (1906), Sezary (1908), Boinet (1909), Poncet and Leriche (1912), Parisot and Lucien (1913), Alou (1922), Wiesner (1923) and others). According to these investigations the suprarenals react by hypertrophy in cases of feeble or slowly developing infection, and by sclerosis and atrophy in cases of severe tuberculosis. In many cases tubercle bacilli could not be detected in the affected adrenals, therefore these changes can only be explained by the influence of the poisons of the bacilli. True nodular tuberculosis of the suprarenals has also been described on several occasions. According to Poncet and Leriche, Lucien and Parisot, and others, the clinical symptoms which may be ascribed to suprarenal disturbances in tuberculosis (apart from true Addison's disease) are the following: vasomotor disturbances, low blood pressure, palpitation of the heart, inclination to collapse, pigmentation of the skin, easy and pronounced sun-burning, muscular weakness,

and general asthenia, increased sensibility to cold, and psychic depression.

The above facts show that the changes in the adrenals indicate their deficiency in severe or chronic infectious diseases and intoxications. Their hypertrophy and increased secretion in cases of feeble or temporary infection or intoxication suggest their antitoxic function. This is shown more clearly by the experiments of Lewis (1921–22) and Scott (1924). Rats are among those animals which survive the removal of both adrenals. Lewis has found that double adrenalectomy increases the sensitiveness of rats to codeine, papaverin curare, cobra venom, veratrin, digitoxin, adrenalin diphtheria toxin, and especial morphine. For instance, the minimal fatal dose of morphine for operated animals was 400–500 times less than that for the controls. This decreased resistance in rats appeared immediately after the operation, but after some time it diminishes gradually and completely disappears. A mixture in vitro, or a previous injection of a watery extract of suprarenals, has not given protection against poisoning. Scott (1924) found that the resistance of rats to intoxication by dead streptococci or staphylococci was greatly decreased after double adrenalectomy. For instance, a dose could be obtained that was invariably fatal to adrenalectomised rats (before hypertrophy of the accessory glands), but never killed control rats. Scott thinks that this decreased resistance is dependent upon a functional insufficiency of the adrenal cortex. Oppenheim (1901) and Stewart and Rogoff (1922) could not obtain the same results in cats and guinea-pigs. Webb, Gilbert, Hartwell, and Ryder (1920) could not find in the changes produced after inoculation with tubercle bacilli a definite difference between adrenalectomised and control guinea-pigs, the only difference noted being a slightly earlier enlargement of inguinal glands in the operated animals. Attempts were made to utilise this antitoxic influence of the adrenals in the treatment of tuberculosis. Renon (1912), Sergent, Lereboullet, Lucien and Parisot (1913) draw attention to the satisfactory results obtained in tuberculosis by adrenal opotherapy.

2. *Sexual Glands.*—There is no doubt that the sexual glands have an internally secreting function. After removal of the sexual glands in both men and animals a change is noticed in the external appearance and the psychology, and in the striking involution of the sexual organs and of many secondary features of sex (provided castration is performed at an early age). These facts alone are sufficient to place the testes and ovaries in the group of endocrine glands. Steinach's experiments (1912) on the cross-grafting of ovaries and testes in animals of the opposite sex, also his experiments (1920) with the ligature of the vas, and the experiments of Voronoff (1923, 1924) and Thorek (1924) with testicular grafts supply evidence of the fact that the sexual glands produce an internal secretion. Steinach's experiments on rats, Sand's (1921) on dogs, and Voronoff's on goats and rams suggest that a ligature of the vas or a transplantation of the testes from a young animal may increase for a limited time some general and sexual force in old animals.

Brown-Séquard (1889) was the first to perform (on himself) dynamometer measurements of muscular strength after testicular injections. These raised his strength from 34 to 41 kg.—i.e., Brown-Séquard at the age of 72 years had regained the force which he had at the age of 26. Copriati (1892) confirmed the above results, using Mosso's ergograph. Very elaborate and exact observations by Zoth (1896) and Pregl (1896) showed that subcutaneous injections of a testicular extract combined with muscular exercise increase the muscular strength by about 50 per cent. as measured by the ergograph. Loewy (1910) found that after injections of spermin the increased oxygen consumption, which is a sign of muscular fatigue, decreases in a marked way. From all these experiments it may be concluded that the sexual glands have a stimulating influence upon the general strength of the animal, and especially upon the sexual organs and their function. On the basis of these experiments several authors (K. Sand (1922), Benjamin (1922), Schmidt (1922), K. Walker and J. Lumsden Cook (1924) and others) in recent years have employed Steinach's operation on human subjects. Many senile patients were among those treated. The conclusion which may be drawn from all these observations is stated by Walker and Lumsden Cook as follows:—

> "At the present there is insufficient material on which to base a decision as to the value of vasoligature as a means of treatment in man. The results of operation appear to have been capricious, although numerous cases are reported in which benefits accrued."

The observations of Voronoff (1920), Stanley (1922), Thorek (1924), Nixon (1924), and Walker (1924) have shown some beneficial effects after the transplantation of the testes of animals or men into patients suffering from senility or other diseases with signs of eunuchoidism. Usually this improvement, when in senile patients, was shown by an increase in appetite and in mental and muscular strength and the disappearance of constipation.

The rôle of the sexual glands in infectious diseases and in intoxications has been very little investigated. Vincenzo and Marcozzi (quoted by Poncet and Leriche), working on animals, obtained a sclerosis of the testicles in experimental tuberculosis and in poisoning with tuberculin. Ancel and Bouin (1905), on the basis of their experiments, conclude that hypertrophy of the interstitial gland of the testicle is seen in the first stages of infection and of intoxication (tuberculosis toxin included). In cases of very acute or chronic and severe infections (tuberculosis) or intoxications, the interstitial testicular glands tend to atrophy. Davis (1922) found the testicles degenerated in various infectious diseases in man. Hansemann (1895) noticed a marked increase in the number of interstitial cells in many cachectic conditions, and quite regularly in chronic tuberculosis, cancer, and syphilis. Poncet and Leriche draw attention to the degeneration of the sexual glands in human tuberculosis. They think that tuberculosis results in a slow castration produced by the tuberculosis toxin. Poncet and Leriche, Hollos (1914), Pierry (1910), Costa (1905) and others have often seen symptoms in tuberculosis denoting disturbances in the internal secretion of the reproductive glands. Sexual maturity either develops too early or there is a state of infantilism with a hypoplasia of the reproductive organs. The specific habitus (long thin limbs with undeveloped muscles) of a consumptive is, according to Poncet and Leriche, due to disturbances in the function of the interstitial glands. Disturbances in menstruation are also a frequent symptom of tuberculosis.

Cristofaletti and Thaler (quoted by Warnekros) tried to discover the rôle of the sexual glands in the resistance of the animal to tuberculosis by experiments with castration. But they did not find any marked difference in the time the castrated and normal guinea-pigs survived when infected with tuberculosis. Neither did the post-mortem examination give sufficient evidence that castration had any influence upon the development of tuberculosis. Warnekros, however, objects strongly to these experiments because they are performed on unsuitable animals; guinea-pigs being too highly sensitive to tuberculosis and surviving too short a time. At present, opinion is not agreed upon the effect of total hysterectomy with castration on tuberculosis in pregnancy. The aim of this operation is to lower the metabolism and produce fattening.

Henkal (quoted by Warnekros) noticed the beneficial effect of castration (total hysterectomy) in eight pregnant women suffering from tuberculosis. Warnekros (1912) also published his own observations on the effect of total hysterectomy on tuberculosis in pregnancy. Out of 34 cases 7 died during the first and beginning of the second year after the operation. Improvements were noticed in all the other patients; they felt stronger, increased in weight (sometimes only temporarily), and the local symptoms in the lungs disappeared or greatly diminished. Warnekros found an improvement in all the symptoms, diagnosed by auscultation, percussion, and X ray. However, the results of the operations by Henkal and Warnekros might be better explained by the interruption of pregnancy, because it is very improbable that normal secretion of the stimulating gland is of any use and even harmful in an infection. Moreover, a histological examination of the sexual glands in chronic tuberculosis reveals frequent degenerative and atrophic processes in them; hypertrophy of the interstitial gland was found only in the early stages of tuberculosis or in mild forms of the disease. Therefore, it is possible to consider the more frequent lowered activity of the sexual glands in tuberculosis, which, Poncet and Leriche say, finally "castrates" the patient by means of tubercle toxins. In spite of this "toxic castration" consumption is not cured or even ameliorated. In the time of Brown-Séquard an attempt was made to treat consumptive patients with "testicular liquid," and some satisfactory results were obtained. The general well-being and strength as well as the local symptoms of the patients showed varying degrees of improvement (Victorov (1891), Maximovich (1891), Henocque (1892), Ouspensky (1896)).

Technique Employed in Present Investigation.

When all the above-mentioned facts were considered it seemed promising to administer preparations of sexual glands + adrenals to tuberculous patients with symptoms of deficiency of internal secretion of sexual or adrenal glands to enable them to overcome this disease. It is obvious that all the operative methods used to provide the patient with the necessary internal secretions of the sexual glands have many limitations. Therefore, it is most desirable to discover a suitable and effective preparation for oral or subcutaneous administration. Since the first observations of Brown-Séquard (1889) on himself, many kinds of testicular and ovarian preparations have been used for the treatment of patients. For general practice, firms of to-day offer a variety of such preparations for oral as well as for subcutaneous administration.

But the results obtained with these are contradictory, and differ much from those described by Brown-Séquard (see Biedl). For subcutaneous injection, the founder of organotherapy used freshly prepared extracts of testes in water and glycerine solutions. These extracts contain an excess of destroyed cell products which produce an unfavourable local and generalised reaction in the patient. Therefore, commercial firms stopped preparing them and replaced them by harmless, but at the same time much less active or sometimes even inactive preparations. Most of them are prepared either by desiccation of the gland tissue (for oral administration), or by precipitation of the proteins and sterilisation of a watery extract of the gland (for subcutaneous injection). Although some improvements in patients after using these preparations are described (Biedl), it is impossible to avoid the objection that the procedure necessary for desiccation, precipitation of proteins, and sterilisation of glandular preparations may destroy or weaken the active principles of the sexual glands. I therefore decided to try a glycerine emulsion for oral administration prepared from perfectly fresh glands. A possible objection to this is that the active principle of glands could be destroyed by the autolysis, which could take place in a glycerine solution. This I tried to avoid by preparing the emulsions very often and by keeping them cold. The method of preparation was as follows.

Testes and adrenals from cattle were used. The glands were brought straight to the laboratory immediately after the animal was killed. They were ground in a "Latapie broyeur" (large model) and emulsified in glycerine in the proportion of 1 part of gland to 2½ parts of glycerine. One part of ground tissue contained 1/8–1/10 adrenals and 7/8–9/10 testes. For therapeutic treatment ½–2 teaspoonfuls were given once or twice daily according to the reaction of the patient.

I have tried this extract on myself for several weeks and have not noticed any harmful effects. In the following text the glycerine emulsion of testes and adrenals will be called "A.T. Emulsion." At first my aim was to administer the A.T. emulsion only to those patients who suffered from tuberculosis with symptoms of deficiency chiefly of sexual glands. But it was difficult to find a sufficient number of suitable cases in hospitals because marked changes in the external appearance can only be seen in those in which deficiency started at an early age. I therefore decided to try the effect of A.T. emulsion also on patients without obvious signs of sexual deficiency.

The above-mentioned treatment of the patients was kindly carried out and the results obtained checked by Dr. M. Paterson, medical superintendent of Colindale Hospital, with the assistance of Dr. M. H. Logg, on 50 patients in Colindale Hospital; by Dr. F. B. Hobbs and Dr. A. I. McLaughlin on 11 patients in the City of London Hospital; by Dr. J. Watt, medical superintendent of the King George V. Sanatorium on three patients; by Dr. M. McDonald on one patient in the Tuberculosis Dispensary of Greenwich; and by Dr. R. C. Wingfield, medical superintendent of the Brompton Hospital Sanatorium at Frimley, on five patients. The treatment of the senile patients was kindly undertaken by Dr. J. A. Lumsden Cook at St. Mary Abbots Hospital.

I was permitted to choose the most suitable patients, to suggest the dosage of the emulsion, and during my visits to the hospitals to follow the results obtained. My sincere thanks are due to my colleagues for their accurate and elaborate observations and for permission to use extracts from their reports for the following short summary.

Observations on Tuberculous Patients.

Colindale Hospital.—50 patients, 17 of whom have some features of deficiency of sexual glands. Out of 12 patients with *medium advanced* disease two were between 18 and 21 years old and ten between 27 and 45. The treatment with emulsion lasted 20–35 days for five patients, 41–60 days for three patients, and 80–112 days for four patients. The dose of A.T. emulsion was 1–2 drachms daily.

The condition of the patients at the end of the treatment was as follows. Improvement in four patients, stationary condition of disease in four patients, and another four patients became worse, three of whom died. In a *definitely advanced* stage of tuberculosis were 19 patients: five were 18–25 years old, ten were 26–40, and four were 41–61. The treatment with the same dose of A.T. emulsion lasted: 20–40 days for six patients, 41–65 days for two patients, and 80–145 days for 11 patients. At the end of the treatment their condition was as follows. Six patients improved, six remained stationary, and seven became worse, three of whom died. In a *very advanced stage* of tuberculosis were 19 patients. Five were between 17 and 25, 11 between 26 and 40, and three between 41 and 44 years old. The treatment (the same dose) lasted: 4–14 days for seven patients, 21–40 days for four patients, 41–60 days for four patients, and 61–110 days for four patients. Their condition at the end of the treatment was as follows. One patient improved, three remained stationary, and 15 became worse, ten of whom died. Seven patients, from whom no conclusions can be drawn, must be excluded, because they were only under treatment for 4–14 days; six of them died during this time.

It is impossible to conclude that there are any constant or definite beneficial effects of A.T. emulsion on tuberculous patients from the observations made in Colindale Hospital. The improvement in nearly all cases could be explained by the sanatorium régime The improvement found in some cases which could be associated with administration of the extract was of a temporary character. In some patients ingestion of the emulsion produced headaches or sickness.

City of London Hospital.—Eleven patients were treated, detailed records of eight of whom are available. They were between the ages of 17 and 26. Treatment of four patients lasted 17–29 days and of the other four 40–70 days. Four patients were in a medium advanced stage of the disease, three definitely advanced, and one very advanced. At the end of the treatment the condition of disease had improved in four patients, remained stationary in three, and became worse in one, who died.

Of the four who showed improvement one is definitely attributable to the emulsion. Therefore, as this case is typical, I will quote Dr. McLaughlin's original report. "Patient was admitted on Sept. 3rd, 1923, and he had signs of considerable tuberculous disease with cavitation of the upper lobe of the left lung, also his right upper lobe was affected. There was considerable activity, his pulse-rate varying from 104–130, the temperature from 101–97·6°, and his sputum 1 oz. in 24 hours; tubercle bacilli were found in the sputum; his weight on admission was 7 st. 8 lb. 10 oz. He exhibited the typical signs characteristic of imperfect testicular development, and he shaved once a week. During the first three weeks of his stay his condition had not varied much and he increased 2 lb. in weight. During the next three weeks his temperature remained on a lower level and his pulse-rate continued to be rapid and he lost 1½ lb. in weight. Seven weeks after his admission he was put on the A.T. emulsion and his weight immediately started to increase; in a fortnight he had gained 5 lb., and he experienced a remarkable feeling of well-being, and in two months he gained 6 lb. and was obliged to shave three times a week. His pulse-rate was considerably slower and varied from 85–95. After two months the A.T. emulsion was stopped and although the patient felt well in three weeks he had lost 4 lb. He has now been transferred to a sanatorium under the Essex County Council." No signs of any negative influence of the emulsion were observed in the City of London Hospital.

King George V. Sanatorium and Greenwich Tuberculosis Dispensary.—These patients have some features of eunuchoidism—long thin limbs, small penis and testes, slow hair growth, high voice, and in two decreased sexual desire. The pulmonary tuberculosis was in a medium advanced stage in three cases and extensive in one case. The age of three patients varied between 17 and 22 years and the fourth patient was 40. In one case the treatment lasted 75 days, and in the other three patients for 125–150 days. The dosage of the emulsion was as mentioned above. At the end of the treatment two showed moderate improvement, one temporary improvement, and one, with extensive tuberculosis, remained stationary. In these cases the improvement could not be ascribed to the emulsion treatment only, but to the sanatorium régime as well. But there were definite changes in the sexual features of three patients due to the influence of the A.T. emulsion. The hair of all three patients began to grow more quickly, one patient's high voice broke, the small and soft testes of another became harder, and sexual desire was increased in two patients. No signs of any negative influence of the emulsion were observed.

Brompton Hospital Sanatorium at Frimley.—Five patients were put on A.T. emulsion, but in three cases the treatment was discontinued after a few days. In one patient it seemed to increase the attacks of pain due to intestinal ulceration, in another nervousness was apparently increased, and the third patient complained of indigestion. The two remaining patients, one with extensive, the other with slight tuberculosis, were treated for four weeks. Subjectively the patients expressed the opinion that they felt better and more energetic, but there were no signs of objective changes in the disease. The disease spread rapidly to the other lung in one patient in spite of the fact that he felt better.

Results in Tuberculous Patients.

From the results obtained from all the above-mentioned hospitals the conclusions are: 1. The ingestion of a glycerine emulsion of testes and adrenals did not improve pulmonary tuberculosis in a definite and constant way. 2. In those patients, whose improvement was probably and in one case (quoted above from Dr. McLaughlin's report) was certainly due to the emulsion, the change was only temporary. 3. By this treatment in some cases of eunuchoidism symptoms of a deficiency of the internal secretion of the sexual glands were slightly improved.

Observations on Senile Patients.

Fourteen patients were put on the A.T. emulsion treatment. Their ages varied from 64 to 94. There was also one aged 45 who showed signs of precocious senility. The duration of the treatment was 3–5 months. The emulsion was given once or twice, one half to two teaspoonfuls daily. Six patients died from different accidental diseases or from senility during the period of observation. The patients were thoroughly examined several times before, during, and after treatment by Dr. Lumsden Cook. Psychological and dynamometer muscular tests were performed before and at the end of the treatment on the six treated patients as well as on the 10 controls by Dr. C. M. Davey and Dr. T. Gourland, under the kind direction of Prof. C. E. Spearman. I wish to express my sincere gratitude to my colleagues for their kindness in undertaking this elaborate work and for permission to make extracts from their reports for this communication.

With the kind permission of Dr. Lumsden Cook I followed the results obtained on the above-mentioned patients during the whole time they were under observation.

General observation of the patients treated with A.T. emulsion did not reveal any considerable change in their condition.

Two types of *psychological tests* were used, those testing (1) general intelligence, and (2) memory and memory association. As most of the patients could neither read nor write, the first type consisted of classification tests, analogies, sequence, completion, and Binet's memory-drawing test. The memory tests were pictorial and consisted of a series of pairs of well-known objects. After the patient had been shown the first half of the series he was asked to give the names of any he could remember. He was then shown one picture of the pair and asked to name its companion. The second half of the series was then given in the same way, and finally the patient was asked to name as many objects as he could of the whole series. A second series of different pictures was given two months later (at the end of the treatment).

The results obtained in the tests of *general intelligence* of 10 control seniles:—

Total number of questions when tested—

First time.			Two months later.		
Right.	Wrong.	Omitted.	Right.	Wrong.	Omitted.
184	95	21	177	85	38

From these results it can be seen that the correlation between the two sets of tests is to be relied on and that the second has not proved to be easier than the first. If, then, there should be any appreciable difference in the results of these tests when applied to other seniles before and after treatment it may be legitimately concluded that this difference was not due to the inefficiency of the test as a measure, but to an improvement or decline in the general intelligence of the patients treated.

The results obtained with six patients treated with A.T. emulsion were as follows:—

Total number of questions—

Before treatment.			After treatment.		
Right.	Wrong.	Omitted.	Right.	Wrong.	Omitted.
80	73	27	95	61	24

Comparing these results with those of the control seniles it may be concluded that the seniles after the treatment with emulsion have shown a slight general improvement.

Memory Tests.—In the control group of patients total number of questions right for:—

During first test.		Two months later.	
Memory.	Association.	Memory.	Association.
125	27	103	17

In the patients treated with A.T. emulsion:—

During first test.		Two months after treatment.	
Memory.	Association.	Memory.	Association.
80	26	111	28

The memory tests show the same results as the intelligence tests—namely, the control seniles appear to be going slightly downhill (especially those who are very aged) and the treated seniles after treatment have shown a decided improvement.

Dynamometer Muscular Tests.—A Cheron and Verdin dynamograph was used for the tests and the following figures are those indicated on its scale during the pressure on the knob of the apparatus by the patient's hand. The following table gives the average results for each hand of six seniles before and after treatment with A.T. emulsion:—

No.	First test.		Second test.	
	Right hand.	Left hand.	Right hand.	Left hand.
1	37·2	35·0	42·0	45·2
2	30·2	20·4	32·0	25·4
3	30·0	24·6	24·8	24·0
4	22·2	22·4	25·0	26·0
5	12·2	8·4	13·2	9·0
6	31·8	31·4	31·2	29·2

In this test patient No. 1 has shown a definite improvement, Nos. 2 and 4 slight improvement, Nos. 5 and 6 practically no change; the right hand of No. 3 has lost some force.

Results in Senile Patients.

It is possible to conclude from all the observations made on senile patients that: 1. The ingestion of a glycerine emulsion of testes and adrenals has only produced a slight improvement in their general intelligence and memory and in some patients in their muscular strength. 2. Comparing the results obtained in senile patients under the above treatment with those obtained by Brown-Séquard's subcutaneous injections, by Steinach's vasectomy, and by transplantation of testes, it is clear that the method—i.e., by the mouth, but not the idea of the special organotherapy—is of no great value.

General Conclusion.

Observations made on 70 tuberculous patients and 14 seniles indicate practically no efficiency in the method of oral administration of preparations of testes and adrenals.

The grant of the Medical Research Council and the hospitality of the laboratories of the Lister Institute have enabled me to carry out this work and to them my thanks are due. I wish also to express my sincere gratitude to Prof. C. J. Martin for his continuous support of this investigation.

MYOMECTOMY AS THE TREATMENT OF ELECTION FOR UTERINE FIBROIDS.*

BY VICTOR BONNEY, M.S., M.D., B.SC. LOND., F.R.C.S. ENG.,

SURGEON TO CHELSEA HOSPITAL FOR WOMEN; ASSISTANT GYNÆCOLOGICAL SURGEON TO THE MIDDLESEX HOSPITAL.

THREE years ago I read a paper before this Section [1] in which I described the results of a consecutive series of 100 myomectomies, and as the outcome of that experience urged a more extensive adoption of the operation so as to include in its scope many of the cases of fibroids commonly dealt with by hysterectomy. Since that publication, and in consonance with it, I have continued the practice of the operation on an increasingly wide scale, so that in three years I have accomplished a further series of 120, the results of which I now report with the object of showing that the main thesis of my previous paper—namely, that in a large proportion of cases of fibroids the uterus can and should be conserved, is sound. So much, indeed, have my views of three years ago strengthened that in my present title I describe myomectomy as the treatment of election for uterine fibroids. I do not mean to imply by that that myomectomy should ever entirely supersede hysterectomy, for no matter how expert we may become at the former operation, and in spite of results far surpassing those obtained up to now, there will always be a certain number of cases in which removal of the uterus is indicated because, apart from the fibroids, it itself is diseased. What I am endeavouring to convey is that conservation of the uterus should be the ideal to be aimed at by the surgeon whenever the organ, apart from the tumours, is reasonably healthy, as it is in the major proportion of the cases. For the compassing of this end two things are necessary, the surgeon must make himself expert in the operation, and the patient must be sent to him before she is so bloodless that it is imperative to stop the periods altogether.

Objections to Myomectomy.

The objections that have been raised against this extension of the scope of the operation are mainly these: (1) that it is often a more dangerous procedure than hysterectomy; (2) that there is considerable likelihood of more fibroids developing; (3) that where menorrhagia is the outstanding symptom it may persist in spite of the removal of the tumours; and (4) that the conserved organ is so damaged that it is functionally useless.

I hope to convince you that none of these objections can be maintained. My new series of 120 operations represents an average of 40 myomectomies performed yearly, so that the patients have not been cautiously selected. I have, in fact, performed the operation in every case in which I felt that conservation of the uterus would be a boon to the woman, irrespective of the number or the position of the fibroids in the uterus.

Number of Tumours Removed.

* Read before the Section of Obstetrics and Gynæcology of the Royal Society of Medicine on Nov. 5th, 1925.

[1] THE LANCET, 1922, ii., 745; Jour. of Obstet. and Gynæcol., 1922, xxix., No. 4.

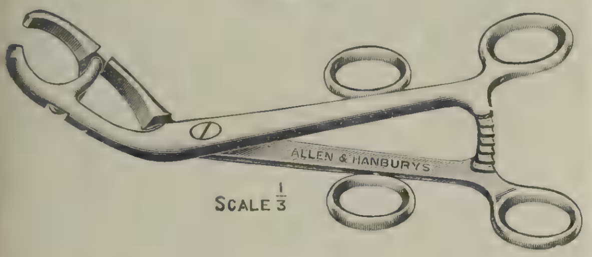
In the above table I have set out the number of tumours removed at each operation. The figures in brackets are the corresponding figures from my old series.

The myomectomy, therefore, was "single" in 47 cases and "multiple" in 73 cases of the new series, and the greatest number of tumours removed from the uterus at one operation was 80.

Technique.

The successful removal of so large a number has been rendered possible by the use of the clamp invented by me (Fig. 1).[2] It acts as a tourniquet applied to the lower uterine segment and controls both uterine arteries at once, so that when the ovarian vessels are temporarily compressed by a ring forceps on either ovario-pelvic ligament the circulation through the uterus is entirely stopped, and the operation becomes bloodless. This is an immense gain, for it not only renders many myomectomies possible which previously were impossible, but in all these operations it permits the surgeon to proceed with the enucleation and subsequent reconstruction of the uterus unhampered and unhurried by the constant oozing of blood which was the chief difficulty previously. The clamp is applied from the front through the lower end of the abdominal wound, and *it is important to put it in so that both round ligaments are included in its grasp*, for otherwise it may slip down the cervix below the point where the uterine arteries enter the uterus. As the enucleation is proceeded with and the uterus shrinks it may need tightening up a notch or two, or even readjusting, and in cases where the supravaginal cervix contains a fibroid this must be enucleated before the clamp is applied. It should not be taken off until the uterus is completely sutured. On its removal the organ temporarily flushes up just as a limb does after a tourniquet is removed and some oozing may start from the suture holes. This usually stops as the flush subsides, but any point that persistently bleeds must be underrun with a mattress suture.

FIG. 1.



As regards the general technique of the operation I have little to add to what I previously described. I continue to remove all the tumours if possible through a single anterior incision in the uterus, and afterwards in many cases either ventrofix the uterine incision, or shorten the round ligaments, or bring a flap of the loose peritoneum covering the lower uterine segment up to the top of the anterior surface of the uterus, like Pesalozza's operation for retroversion. The object of all these manœuvres is to prevent intestine adhering to the sutured uterus. The various devices which I described and illustrated [3] for getting access to fibroids in the back wall of the uterus and for closing the enucleation cavities have all continued to prove of value. The "hood" operation for large posterior fibroids has been most satisfactory, and a good many of the present series have been carried out that way. I also frequently employ the "transcavity" route for posterior tumours. Opening the uterine cavity has not been followed by any ill-results and I do it in most of the operations to prevent small submucous tumours being overlooked. In the closure of the major enucleation cavities and in reconstructing the uterus I employ silk for the main mattress sutures because I believe it to be the safest. Too rapid absorption of catgut leads to opening up of the cavity it closes and bleeding occurs into the space. This is dangerous, for the hæmatoma may become infected. For sutures of lesser importance I use catgut.

Objections to the Extended Operation.

Dealing now with the various objections that have been raised against the extended operation :—

Risk as Compared with Hysterectomy.—There were three deaths in this series of 120 operations. Two of the deaths were due to that baffling condition, paretic obstruction of the intestine. Both these patients were elderly women, and the object of conserving the uterus was the same in each case—viz. to ventrofix it and make it act as an artificial ligament to hold up a prolapsed vaginal vault. Neither myomectomy was "large," either in the sense of its difficulty or of a large number of tumours removed. One of the patients had the abdomen reopened before death, and a post-mortem examination was made on the other. In neither case was there found any obvious cause for the intestinal paresis and distension. The disaster may happen after hysterectomy or any other abdominal operation, and in the present instances cannot be attributed to the fact that myomectomy preceded it any more than another operation. The third death was due to pulmonary embolism, which occurred in the third week of what, up to then, had been a perfect convalescence. In my earlier series of 100 operations I had two deaths, one due to post-operative hæmorrhage discovered too late, and one due to peritonitis, secondary to post-operative oozing from the uterine wound. Both these deaths were directly dependent on the myomectomy as such.

There were thus five deaths in 220 operations—an operative mortality of 2·09 per cent. Though series of 100 or more consecutive hysterectomies for fibroids without a death have been recorded a good many times, yet the general mortality of this operation is not so low as these happy runs of luck would suggest. Taking hospital practice all round the mortality of hysterectomies for fibroids, when carried out by surgeons expert in that operation, is probably about the same as I have quoted for myomectomy. Myomectomy at present requires on the average a higher degree of skill than hysterectomy, but as practised on a wholesale scale it is a newer operation, and like all operative innovations presents difficulties which the experience accruing from increasingly widespread adoption will circumvent or do away with. Thirty years ago every hysterectomy bristled with difficulties; nowadays only a very small proportion of these operations extend a trained gynæcological surgeon. Convalescence after myomectomy is usually smooth, but on the average, as compared with hysterectomy, there is more pyrexia in the first week, due probably to absorption from the enucleation cavities. I have not had any trouble from the silk sutures in the uterus.

Recurrence of Fibroids.—Turning to the second objection that new fibroids are likely to develop in the conserved uterus, I have no hesitation in calling it an unsubstantial bogy, provided the operation is performed so that every tumour down to the smallest seedling is removed. Two of my earliest cases exhibited nodules the size of marbles some years after their operation, but they were performed at a time when I was not thorough in searching for and removing every seedling. I am unaware of any others. This freedom from recurrence has indeed surprised me, and led me to recast my opinion on the age of genesis of these tumours. I believe now that the seedling is, as a rule, formed much earlier in life than has been hitherto believed, probably in the 'twenties, and that the formative agent, whatever it is, is not operative continuously but ceases to act after a period.

---

[2] Described in Jour. of Obstet. and Gynæcol., 1923, xxx., No. 3.

[3] Jour. of Obstet. and Gynæcol., 1922, xxix., No. 4.

Persistence of Menorrhagia.—The third objection that menorrhagia may persist in spite of the removal of the tumours is equally untenable. I have never yet had to operate on any of my patients for continuance or reappearance of excessive bleeding. Where the uterus is greatly hypertrophied from clothing a large fibroid or mass of fibroids it is necessary to cut it down to a manageable size before returning it to the abdomen, for though involution occurs after myomectomy, as after parturition, it is unsafe to trust too much to that. The uterus when sutured should, however, be a little bigger than normal, otherwise, when involution is complete, it will be abnormally small. In such a case the first period or two after the operation will be freer than normal, but decreasingly so as involution proceeds, until the normal is attained.

Function of the Conserved Uterus.—The fourth objection that the uterus from which a number of fibroids has been removed is functionally useless is also fantastic. To my knowledge, a number of my patients have subsequently conceived. Natural delivery is possible even after many tumours have been removed. In my previous paper on the subject I recorded such a delivery after I had enucleated 21, and quite recently Fletcher Shaw published a similar case from whom he had previously enucleated 23.[4] There is probably no tissue in the whole body that heals so perfectly as uterine muscle. I have examined many of my patients a year or more after the operation, and used to be surprised how healthy the uterus felt, but I am getting accustomed to that. Several times I have had the opportunity of inspecting the conserved organ through an abdominal incision, and its appearance confirmed the impression of normality given by previous bimanual examination. Lastly, on two occasions I have tested the tubes by inflation some years subsequent to myomectomy and in both patients they were patent. From one of these women I had removed 17 fibroids. Menstruation a year from the operation has invariably become natural in periodicity and amount, and in those cases in which the fibroids were accompanied by dysmenorrhœa their removal was followed by immediate disappearance of the pain. There is a well-marked class of case in which quite small fibroids in the uterus give rise to very severe monthly pain without other symptoms, and in such the results of myomectomy are most gratifying.

The Uterus in Relation to Ovarian Activity.

There remains to speak of a further function of the uterus—namely, its influence in maintaining ovarian activity, a function which, being lost as the result of removing the organ, is followed by climacteric symptoms due to ovarian atrophy some years earlier than would have happened if the uterus had not been removed. This function is preserved by myomectomy.

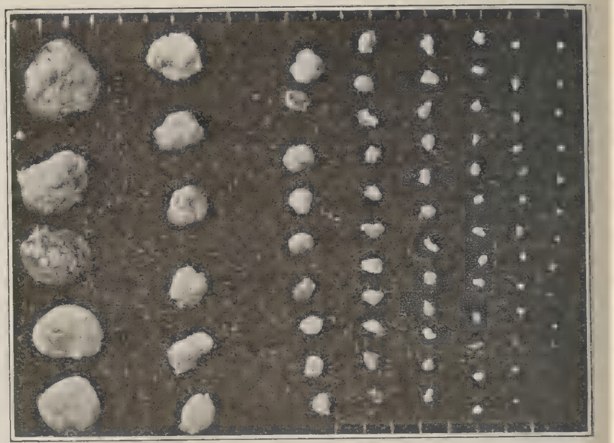
The idea then that the conserved organ will probably be an incubus to its possessor on account of hæmorrhage, discharge, or pain may be dismissed as an example of that unsafe habit of theorising without founding the theory on practical experience which more or less besets all of us.

Clinical Illustrations.

Let me finally record some of the achievements which myomectomy makes possible.

The largest number of fibroids that I have as yet enucleated at a single operation is 80. This patient was an unmarried woman aged 35. She was engaged to be married and was sent to me with the express purpose of having her uterus saved if it was possible. The abdominal tumour was the size of an eight months' pregnancy and was so symmetrical that I thought it probably was composed of a very large solitary fibroid, with perhaps one or two smaller ones. On opening the abdomen it proved to be the great congeries of tumours shown in the photograph (Fig. 2), which were impartially distributed in the front, back, and side walls of the uterus. I was able to enucleate all these with a very small loss of blood, thanks to the myomectomy clamp I have described, and I reconstructed the uterus so that there is no obvious reason why when she marries she should not conceive.

FIG. 2.



Eighty fibroids enucleated from a uterus at a single operation. Each division of the scale represents an inch.

A year ago I had a very remarkable case of an unmarried girl of 24 with a huge mass of fibroids.[5] I enucleated these to the number of 52, and a week or two since she came up at my request to be examined. The uterus felt absolutely normal, and her periods, which ceased entirely for three months after the operation, are now regular in onset and natural in duration and quantity.

Another unmarried girl of 22 was sent to me with an abdominal tumour the size of a seven months' pregnancy. It turned out to be a solitary submucous fibroid of the posterior wall which, when enucleated, weighed 5 lb. It had undergone nævoid degeneration and was excessively vascular. This was a case which some years ago I should certainly have treated by hysterectomy to the girl's lasting disadvantage and hurt. Instead I performed a "hood" operation and sent her back to her parents well and whole.

Quite recently I operated on a married woman, aged 38, six months pregnant for the first time, on account of a large mass of fibroids, one of which had undergone acute necrosis. It was necessary to begin the operation by removing the pregnancy through the uterine incision because the situation of the fibroids was such that preservation of the child was impossible. I then proceeded to enucleate the tumours to the number of 22 and, though I have removed a much larger number, these were so awkwardly placed (three of them were embedded in the posterior wall of the supravaginal cervix) that I must admit I was daunted. However, I persisted, and in the end left her with an excellent organ in which the vast chances are she will conceive again. This was a case where a child was very greatly desired both by the wife and husband.

In regard to the preservation of pregnancy complicated by fibroids which have to be operated on, it is usually possible to achieve this when the tumour is solitary or, when multiple, not present in large numbers. Seven tumours is the most I have yet been able to enucleate without disturbing a coexistent pregnancy. Where, however, a large number are present, as in this case, the pregnancy must be treated as an additional tumour and "enucleated" too.

I could give many more examples of the beneficent possibilities of the operation, but I think what I have said sufficiently justifies the title of this paper, and I hope to see the time when every surgeon called upon to operate for this condition will enter upon his task with that conception in the forefront of his mind.

A NOTE ON

MARGOSA OIL IN THE TREATMENT OF CANCER.

By K. K. CHATTERJI, F.R.C.S. Irel.,
MAJOR, I.T.F. MEDICAL CORPS; SURGEON, MEDICAL COLLEGE HOSPITAL, CALCUTTA.

Margosa oil, obtained from the seeds of the nim or margosa tree, has in its composition saturated and unsaturated fatty acids. I commenced my investigations on the oil early in 1917 and later, in collaboration with Prof. R. N. Sen, of the University of Calcutta, the insoluble fatty acids were separated from the oil, and the nature of margosic acid—i.e., the mixed insoluble fatty acids of the margosa oil—was elucidated. On isolating the unsaturated fatty acids the neutralisation value was found to be 185·89 and the iodine value 105·28. The solid acid separated had the neutralisation value 198·12 and iodine value 12, which showed that unsaturated fatty acids were still present in very small quantities. This acid was found to be stearic acid with minute traces of unsaturated acids. The unsaturated fatty acids appeared to consist of oleic acid ($C_{18}H_{34}O_2$) and an acid belonging to the linolic acid series which Prof. Sen declared to be the characteristic fatty acid of margosa oil. $C_{22}H_{40}O_2$ has been suggested for its formula. This acid has been called margosic acid, and it is not known to have been obtained from any other oil.

It has a yellowish colour, is liquid at ordinary temperature, and possesses no optical activity. The sodium and potassium salts are soluble in water; its lead and barium salts are soluble in ether and benzene. It forms about 23 per cent. of the total fatty acids present in margosa oil. At my suggestion Prof. Sen has prepared several salts as well as ethyl ester, allyl ester, and, recently, benzyl ester from the mixed fatty acids.

The evolution of margosate therapy and the sequence of events which narrowed down the field of research and finally centred it in cancer may be interesting from the point of view of cancer research.

In the "Ayurvedas" the cleansing and healing properties of the nim for ulcers are extolled. While testing the antiparasitic and antiprotozoal action of sodium margosate, it was found that in dilute solutions it killed paramœcia, prowazekia, microfilaria, &c. The action of ethyl ester margosic was more potent. Using sodium and potassium margosate therapeutically, it was observed that effects were marked in the granulomatous stages of syphilis (late secondary and tertiary stages), for tuberculous glands and ulcers, in leprosy, and in some varieties of diseases of the skin. As the effect of margosate treatment was rather striking in clearing up the granulomatous conditions, its use was extended to tropical granulomata.

Sodium Margosate, Potassium Margosate, and Ethyl Ester Margosic.

At first I used two of the more soluble salts of margosic acid, sodium and potassium margosates; 2 to 3 gr. (4 per cent. solution) were given. Intramuscular injections caused some local irritation, and intravenous injections caused obstruction in the veins after a few doses.

Ethyl ester margosic is a clear reddish fluid with a fruity aromatic odour and a high boiling-point. It is insoluble in water, but soluble in ether, alcohol, and chloroform. I soon gave up sodium and potassium margosate and brought ethyl ester margosic into use, as I found it superior even to the potassium salt. Ethyl ester does not cause local irritation or irritation to the veins and has no hæmolytic properties. Its margosic content is higher than the salts, and much more so per volume compared to the 4 per cent. solution of the salts that could be used. Being in loose chemical combination it is hydrolysed more readily. Its antiparasitic and bactericidal properties are definitely higher. It seems to influence fat metabolism remarkably, as can be observed from the results obtained from its use in some conditions due to filarial infection.

On testing the blood of many of these patients it was found that there was a variable deficiency in calcium salts in some granulomatous cases, but this deficiency was markedly constant in cancer patients; as a matter of fact, a definite calcium deficiency caused some suspicions of malignancy in cases of granulomatous growths. It is known that the potassium content of the blood of cancerous individuals is above normal, and while calcium has an inhibitive influence on the growth of cancer, potassium acts favourably. In view of these, I gave up the use of potassium margosate and introduced ethyl ester margosic. I gave calcium and parathyroid extract to some of my patients, and I have an idea that improvement was more marked in them.

Ethyl Esters.

Ethyl esters of various oils were prepared, such as cod-liver oil, olive oil, "til" oil, chaulmoogra oil, &c., and a comparative study was made. The ethyl ester of pure margosic acid seemed to have the greatest efficacy; the other oil which approached it in other respects was olive oil. Esters of animal fats and oils were not as effective.

Copper Margosate.

My experiments show that E.E. Cu-margosate has a strong inhibitive effect on the growth of fungi, protozoa, cocci, and other organisms, and that when used therapeutically in the form of local or intravenous injections it induces fibrosis and encourages epitheliation of granulating surfaces. Copper is carried to the tissues with the fatty acid elements; and there is some evidence that copper, like calcium, is attracted to the tissues in which rapid cell division is in progress. The fat and copper in the E.E. Cu-margosate is transported to the tissues, and much is attracted by the rapidly multiplying cells of cancer. Copper gives rise to the formation of fibrous tissue. thus causing barriers and obstructions to the growth of cancer. If the infective origin of cancer is to be taken into account we know that copper has strong antiprotozoal and antibacterial properties, and healthy granulation tissue, fibrosis, and epitheliation follow the elimination of the infective element. In some cases treatment with E.E. Cu-margosate has cleared up the growth and removed all evidences of malignancy. In others this treatment has been supplemented by irradiation by X rays, and in almost all instances it has expedited the process. In my opinion, which I must admit is not based on a very large experience, radiotherapy is indicated for the improvement of local and general metabolism and in order to stimulate lymphocyte activity and fibrosis. The idea of producing caustic or destructive effects on the cells to any great extent by X rays has not appealed to me. In Case 3, epidermoid carcinoma of the leg near the ankle with greatly enlarged femoral and inguinal lymph glands, this combined treatment of the ulcer in the leg and one or two exposures of the glands practically led to their absorption. When the remains of these glands were removed and examined no signs of malignancy were found. This suggests the production of immunising substances, and a heavy dose of exposure like an overdose of vaccine is hardly desirable in a case of cancer. The work of destruction and disposal of the cells could reasonably be trusted to copper and margosate treatment aided by the more desirable therapeutic action of X rays. The action of copper with margosic ester has been shortly described. Minute particles of copper are deposited throughout the neoplastic tissue. It may reasonably be presumed that irradiation of such growths has dual therapeutic effects. The direct action of the X rays accentuates the histological changes produced by copper and the fatty acids, and the rays impinging on the minute particles of copper give it radio-activity and produce a number of small secondary rays in the tissues; the therapeutic effect of the rays is continued and the tissues are kept for a longer period under the influence of these rays than they would be by other methods of irradiation. Ulcers and tumours have been treated by copper ionisation and then irradiated, but it was thought that, as ionised copper is mostly deposited on the surface, they would act as filters. In this case, on the other hand, the particles of copper being dispersed deeper in the tissues, the primary rays impinging on them would be reflected from them as secondary rays and be absorbed by the tissues. The ideal rays would, therefore, be those obtained from a source giving rays which would have the above-mentioned therapeutic properties without producing lethal effects on the tissues.

Clinical Histories.

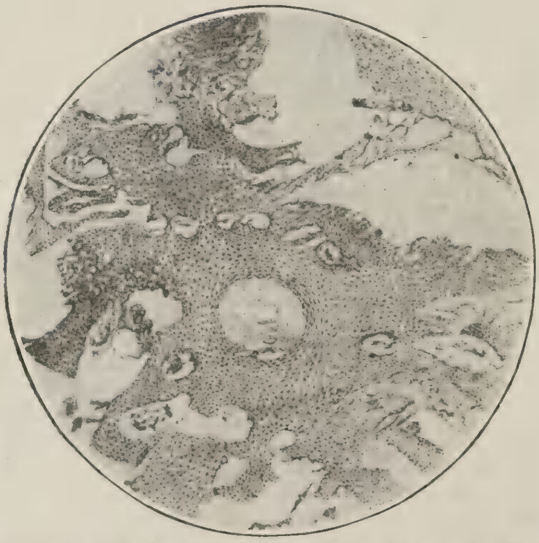
I give here summarised reports of three cases of cancer treated.

CASE 1.—Hindu, male, 26 years. Admitted under my charge in the Campbell Hospital in March, 1922, and transferred to the Medical College Hospital in August, 1923, for a fungating ulcer with foul discharge, and unhealthy granulations involving the anus and perianal area, the whole of the perineum, and the scrotum laterally and in front. The inguinal glands were hard and enlarged. There was much pain, defæcation being particularly painful. The patient had lost weight and was cachectic. Wassermann reaction was negative. A provisional diagnosis of anorectal granuloma tropicum was made.

Treatment.—A piece was excised from the growing margin and sent for pathological examination, and treatment commenced. Fifty-eight injections of E.E. Cu-margosate were given locally and intravenously and intramuscularly. During treatment the following changes were noticed: the general appearance of the granulations was healthier, discharge, discomfort, and pain were reduced, defæcation was easier, evidence of cicatrisation and epitheliation.

First pathological report (before commencing treatment)—"squamous epithelioma" (Fig. 1). As much improvement was noticed with the above treatment it was persisted in, particularly as the end-result of operation was not very bright. Second pathological report after 25 injections: "Epithelioma showing dense leucocytic infiltration between epithelial spaces." Third pathological report after 46 injections: "Under the epithelium a mass of granulation tissue extends deep into the corium. There is no evidence of malignancy" (Fig. 2). By this time processes of cicatrisation and epitheliation had extended from the periphery across the growth towards the anus. After 58 injections the ulcer had completely healed. The surface was covered with cicatricial tissue and epithelium; pigmentation of this surface was in progress. This patient was not treated by radiations.

FIG. 1.

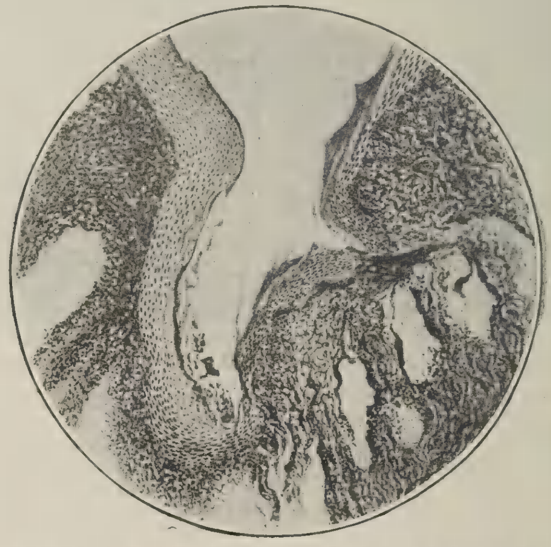


Microphotograph of section of growth before treatment. Pathological report: "Squamous epithelioma."

CASE 2.—Hindu, male, 19 years. Admitted under my charge in the Campbell Hospital in June, 1922, and transferred to my wards in the Medical College Hospital in August, 1923, for a large fungating tumour with a foul discharge in the right parotid region. He was very anæmic, with hæmoglobin content of blood 40 per cent., general condition bad, and a low blood pressure. The tumour was 10 inches in circumference and extended to the angle of the jaw below and displacing the ear backwards (Fig. 3, A). The patient did not consent to operation and it was not pressed because of his bad health.

Treatment.—A piece was removed from the margin of the growth for pathological examination. From June, 1922, till August, 1923, he was put on calcium chloride occasionally, and doses of parathyroid extract. E.E. margosic and E.E. Cu-margosate injections were given locally into the growth and intraglutecally. He also had 24 radiations by X rays. As a result his general condition much improved, and the hæmoglobin value of his blood rose to 80 per cent. The tumour became much smaller and cleaner, there being only a slight serous discharge; cicatrisation and epitheliation were encroaching from the periphery towards the centre of the surface. An attempt was now made to excise the growth with only partial success as it was firmly fixed to the jaw and adjoining structures. The excised portion was sent for pathological examination and the report awaited before deciding on further operation. As this was rather satisfactory, and the raw surface rapidly became covered with epithelium, any idea of further operation was abandoned. The patient continued to improve, no signs of recurrence in May, 1925 (Fig. 3, B).

FIG. 2.



Microphotograph of section of tissue after completion of treatment. Pathological report: "Under the epithelium a mass of granulation tissue extends deep into the corium. There is no evidence of malignancy."

First pathological report before treatment was commenced: "Mixed parotid tumour (malignant)." Second pathological report: "A mixed tumour of the parotid consisting of two main elements, (1) a dense hyaline fibrous tissue, (2) a typical carcinomatous element the cells of which appeared to be altered epithelial cells in masses, with numerous small lumen-like spaces containing mucus; a duct origin is suggested. Tumour does not feel to be highly malignant."

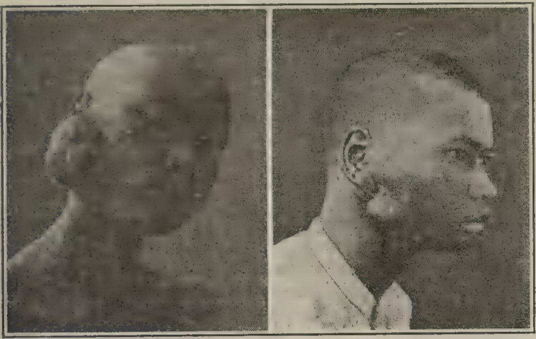
CASE 3.—Mohammedan, male, 55 years. Admitted September, 1923. He was referred to me as a bad case of cancer of the leg, necessitating amputation. The patient, however, wished first to try my method of treatment, and agreed that if no improvement was noticed after two weeks his leg should be amputated. He had a foul fungating ulcer on the mesial aspect of the left leg above the ankle firmly fixed to the lower end of tibia; its diameter was about 4 inches. The femoral and inguinal glands on the left side were enlarged and hard. There was not much emaciation, and the patient was not particularly anæmic. Wassermann reaction negative.

Treatment.—A piece of the growth was sent for pathological examination and treatment was commenced. He had altogether 17 injections of E.E. Cu-margosate and had 16 exposures to X ray mostly of the growth, the glands being exposed only on a few occasions. The ulcer healed up completely. The cicatrix was rather firm and extended for a good extent round the leg. The femoral and inguinal glands were much reduced in size. The remains of the glands were excised and sent for pathological examination. The patient is still under observation; there were no evidences of recurrence up till May, 1925.

Pathological examination of the growth before treatment: "Epidermoid cancer." The lymphatic glands after treatment showed no signs of malignancy.

These three cases have been reported as they were still under observation in my ward when I left Calcutta in May of this year. There were no signs of recurrence. In the third case I apprehended some trouble from the disturbance of venous circulation by extensive cicatrisation which almost encircled the leg.

FIG. 3.



A B

A, Before, and B after treatment.

In some cases I have occasionally scraped and cauterised with thermocautery or electric cautery exuberant and unhealthy granulations. In Case 2 it will be seen that an inoperable growth was rendered operable by this treatment with a satisfactory result. In all cases cicatrisation commenced at the periphery of the ulcer and extended towards the centre, closely followed by epitheliation. Pigmentation appears later at the margins and spreads over the whole surface.

Clinical and Laboratory Notes.

SUDDEN DISAPPEARANCE OF EXTREME ŒDEMA IN CHRONIC NEPHRITIS.

BY A. J. SCOTT PINCHIN, M.D. LOND.,
PHYSICIAN, HAMPSTEAD GENERAL HOSPITAL.

THE following case, as an example of the effect of an acute infection on chronic disease, is of some interest, and appears to be worthy of record.

I. T., female, aged 24, was admitted to the Hampstead General Hospital, July 1st, 1924, with extreme œdema.

History.—She had diphtheria at 8 years of age and ever since her ankles have swollen after prolonged standing, but she had considered herself well till March, 1924, at which time the swelling became persistent and steadily got worse until admission. On admission she had a pale, puffy face and severe œdema extending to above the iliac crests. There was no cardiac hypertrophy, though the second sound over the aortic area was increased. Blood pressure 130/85. Marked diminution in urinary output, much albumin, and granular and epithelial casts. Blood-urea, 40. Concentration test, 2·5–1·9–2·4. Wassermann negative. Urea and other diuretics, salt-free diet, baths, &c., failed to have any effect on her œdema. Tapping of the legs produced only a slight reduction, and the skin was so sensitive that drainage was always accompanied by an eczematous condition of the legs.

As no improvement occurred, my colleague, Mr. Gordon Bryan, decapsulated both kidneys on August 26th. The result was disappointing, and she was transferred back to medical ward on Sept. 14th with no improvement. On Oct. 29th the condition was much worse, much ascites and extensive hydrothorax. The legs were punctured again, and she was kept in the upright position, with the result that the chest was clear by Nov. 12th, the ascites less, but much œdema of the legs and trunk. Thereafter massive doses of urea, puncture, hot air, &c. were used in turn.

April 21st, 1925: She had now been nearly ten months in a water-logged condition and her œdema was about the same as on admission. On the evening of this date her temperature suddenly rose to 101·6° F., and she became extremely ill; there was a red inflamed patch on the right leg but no other signs. By the following morning she had a diffuse erysipelatous condition extending over both legs and most of the trunk. Her fever lasted three days, during which she took no food and was in extremis. Eight days later she was again normal, the urinary output had gradually increased to 90 ounces a day, and the œdema had practically gone. Blood-urea, 16. Urine: trace of albumin, one or two granular casts, no blood. On June 4th no albumin was present and she was fit for convalescent home. She was seen two months later on her return from Torquay. She was feeling almost normal; there was no trace of œdema; the urine contained a heavy trace of albumin but no casts.

Personally, I am at a loss for an explanation of this rapid change; it was certainly allied with the acute disease; whether a cryptic streptococcal infection keeping up the kidney condition was wiped out in the sudden onslaught, or the acute fever opened up lymphatic channels and so broke a vicious circle, or whether to a shock reaction in which one sees so many curious results in so varied a collection of diseases, is a subject for interesting speculation.

My thanks are due to Dr. H. W. Perkins for the pathological investigations.

FAT NECROSIS OF THE BREAST.

BY CECIL ROWNTREE, F.R.C.S. ENG.,
SURGEON TO THE CANCER HOSPITAL.

FAT necrosis of the breast would appear to have been comparatively unknown to British surgeons until Geoffrey Keynes drew attention to the condition at the Section of Surgery of the Royal Society of Medicine,[1] and subsequently published [2] a full description of his case, illustrated by excellent microphotographs, which clearly show the histological features of the disease. The obvious importance of the condition in connexion with the differential diagnosis of cancer of the breast leads me to report the following case.

In October, 1922, I saw an unmarried woman of 31 with extremely fat pendulous breasts, who stated that some months previously she had fallen down and struck the left breast on the ground. No bruise or other evidence of injury was apparent immediately, but two small lumps made their appearance some time afterwards.

Examination revealed two hard nodules the size of hazel nuts, one in each lower quadrant of the left breast. They were situated quite superficially and were definitely adherent to the skin, which was slightly puckered over each of the nodules. There was no retraction of the nipple, no discharge from it, and the axillary glands were not enlarged.

A provisional diagnosis of carcinoma or tuberculosis was made and the nodules were removed for inspection. The tissue proved to be unlike anything I was familiar with, but my suspicion of carcinoma was so insistent that I proceeded to amputate the breast, and sent the specimens to be examined microscopically. The report was as follows: "Cannot make final diagnosis; the tissue is mainly adipose tissue infiltrated with small round cells and a few multi nucleated giant cells. No tubercle bacilli found."

I was chagrined to find that I had probably amputated the breast unnecessarily, but I was particularly disturbed because the sign upon which I have always so greatly depended as almost pathognomonic of cancer—adhesion to the skin—appeared to have let me down, but I recognised that this sign might also occur in tuberculosis, and in spite of the inconclusive pathological report I labelled the case in my notes as "probable tuberculosis" and kept it in my mind for future reference.

The original American paper on Fat Necrosis [3] escaped my notice, but as soon as I saw Keynes's paper I realised that he had furnished me with the explanation of my puzzling case and I sent him my slides, which he kindly examined, and informed me that the histological features were similar to those he had described.

The elucidation of this case naturally led me to search for others of a similar nature, and I have investigated a large number of old notes and sections, but I can find no further examples of fat necrosis in my own experience, nor have any yet been traced in the pathological department of the Cancer Hospital. Mr. Raymond Johnson also, in his Bradshaw lecture on Cancer of the Breast, states that he has had no personal experience of the condition. It is clear, therefore, that fat necrosis of the breast is a very rare disease, but it is none the less important, for it is evident that the condition is almost certain to be confused with carcinoma and treated accordingly—a doubly unfortunate event if, as in my case, the patient happens to be a young woman, and having regard to the traumatic origin of the disease one would expect it to be just as likely to occur in the early as in the later age-periods.

[2] British Journal of Surgery, April, 1925.
[3] Lee and Adair: Annals of Surgery, August, 1920.

It is interesting to speculate upon the progress of events in cases of fat necrosis that are not submitted to operation. All the cases hitherto recorded are based upon microscopic examination of tumours, either definitely diagnosed or strongly suspected to be malignant, and we get no help from them in this particular. Does the mass gradually quiet down and undergo resolution? The fact that the lesion involves the fat overlying or infiltrating the breast and not the mammary tissue itself—a point emphasised by Keynes and clearly shown in my own case—suggests that the damaged tissue may undergo absorption and leave little or no trace.

But to me the chief interest of the condition is the implication of the skin recorded in nearly every case, for this is the one sign above all others upon which reliance may be placed in the diagnosis of malignant disease of the breast. It is, of course, nearly always present in the more advanced cases, but it is frequently present in a very slight degree in quite early cases where the carcinoma is so small that diagnosis would be impossible in the absence of this sign, and I had come to regard it as an almost certain indication of malignancy. A shade of doubt will now be introduced when considering the differential diagnosis of breast tumours which involve the skin, for the possibility of fat necrosis will have to be remembered.

A CASE OF RECURRENT HAIR-BALL OF STOMACH.

By Rufus Harris, M.R.C.S. Eng.,

LATE ASSISTANT SURGEON TO THE GLOUCESTERSHIRE ROYAL INFIRMARY AND EYE INSTITUTION, GLOUCESTER.

The following case is of unusual interest, sufficiently so, I think, to merit publication.

Miss B., aged 35, presented the following history. In 1911 she was operated upon at St. Mary's Hospital, London, for the removal of a hair-ball from her stomach. In April, 1920, she was operated upon by Mr. W. Washbourn, of Gloucester, for a similar condition, and again in June, 1922. When I saw her in October, 1923, she complained of pain and a swelling in her abdomen and loss of appetite of three months' duration.

On examination, a large solid tumour was visible and palpable in the upper part of the abdomen. In view of her past medical history another hair-ball was suspected.

Operation Nov. 11th, 1923, Gastrotomy.—Upon opening the stomach, which was much enlarged, it was found to be entirely occupied by a mass of hair. This extended through the pylorus into the duodenum, and when removed was found to weigh 2½ lb. and measured 20 in. in length. The girth at the largest circumference in the stomach portion was 15 in. Recovery was uneventful and, after giving a solemn undertaking to refrain from the habit of hair-eating, she was discharged as cured. In November of last year the patient once more turned up complaining of a return of her former troubles, and I again removed a large hair-ball. Up to the present I think she remains quite well.

I may add that, apart from her hair-eating habits, this woman is quite normal mentally, being well educated and a very fair musician. She seems to have suffered no permanent ill-effects from her repeated operations since her abdominal wall is firm, and, when her stomach is not full of hair, her digestion is unimpaired.

Exeter.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTIONS OF OPHTHALMOLOGY AND SURGERY.

Plastic Operations on the Face in the Region of the Eye.

A combined meeting of these Sections was held on Nov. 13th, Sir **Arnold Lawson**, the President of the Section of Ophthalmology, occupying the chair.

Mr. **H. S. Souttar** opened the debate from the standpoint of the general surgeon. He said ophthalmic surgeons must have a greater experience of plastic operations around the eye than he had, but one or two methods used by general surgeons in this region might be of interest to ophthalmologists. Many years ago Dr. J. H. Sequeira, in charge of the skin clinic at London Hospital, began to send the speaker cases of hairy mole on the face, a very common condition. When he first had them to deal with he did not realise what the essential difficulty in treating them was—namely, their proximity to the eye. With one exception, all the cases of the kind he had had to treat occurred in children, and he had treated them all by the arm-flap method. For most plastic surgery in which a large flap was needed, the large tubular flap method, as developed by Gillies, was the most potent; but Mr. Souttar still considered that for children the arm-flap method had great advantages—i.e., using the arm as the pedicle for the flap, the arm being extended over the head. He showed slides of a series of cases by means of the epidiascope. In one of them, an extensive mole, a surgeon had attempted to replace part of the mole by a Thiersch graft, a kind of graft quite unsuitable for these cases. These moles could only be adequately replaced by whole-skin grafts, and for a child these were best taken from the shoulder. In one such case, the photograph of which he showed, two flaps were used, the second from the forehead. Here also some ectropion remained at the angle of the eye, and he left, as was his custom in such cases, a small piece of mole there, excising it some time later and putting in a Thiersch graft. In a case of very obtrusive red nævus he succeeded in establishing a normal colour by diathermy puncture.

Mr. **A. W. Ormond** introduced the subject from the standpoint of the ophthalmic surgeon. The major part of the work in these cases consisted of repairing or replacing either one or both eyelids, correcting irregularities of lids after cicatricial contractions which had led to exposure of the globe, entropion, ectropion, epiphora, or deformities of the lid margins, and making or deepening a socket to permit the wearing of a glass eye. The means mostly consisted of modifications of flaps and grafts. With regard to flaps, these usually consisted of the whole thickness of the skin, and were either pedunculated or non-pedunculated, while the pedicle might consist of flat skin, tubular skin, soft tissue, or a square base of skin. Grafts, consisting of epithelial layers only, might be small multiple islands of epithelium placed on a granulating surface, or large areas obtained by Thiersch's method and applied directly on to a raw surface or stretched over a mould. In the case of pedunculated flaps, the pedicle could consist of skin applied with its raw surface to the underlying tissues, and it was employed to support the nutrition of the flap by connecting it with its original bed. Or the skin could be raised and rolled round on itself to form a tube, and in that event the flap could be obtained from a site a considerable distance away from the face.

General Principles in Cutting Flaps.

When flaps were taken from the skin in the immediate neighbourhood of the wound, Jacobovici laid down the following requirements: (1) The pedicle of the flap should be near the site at which the loss of substance had occurred. (2) The long axis of the pedicle should correspond to the long axis of the flap in its new situation. (3) The long axis of the flap should not be too curved, for the elasticity of the skin would cause the detached flap to take the direction desired. Dieffenbach's and Burow's methods of repairing the lids by the shifting of healthy skin in the neighbourhood of the injury had only a limited applicability, and as the contraction might be considerable, the methods might fail. The bed for the reception of the graft should be moist but free from oozing blood, and the graft should fit its bed accurately. There should be immobility and lack of interference for several days. If a whole flap lived and joined up rapidly, the contraction ensuing was not of great degree; it was greater if the edges of the flap suffered. A flap fitting a raw surface with a subjacent bone or cartilage basis would not be found to contract to the same extent as when the bed consisted entirely of soft tissue.

Mr. Ormond said the methods of dealing with a contracted socket were still unsatisfactory. The chief reason was that the substitution of the destroyed conjunctiva was very difficult. Grafts of mucous membrane from mouth or foreskin were with difficulty rendered aseptic, and owing to the degree of their contraction such grafts did not achieve much. He also considered epithelial inlays disappointing when used to enlarge a contracted socket. It would perhaps be well to begin by inserting a cartilage, or paraffin, or a filigree ball into the socket. The implantation of an artificial globe could be carried out as described by Webster Fox. During the war the speaker used cartilage as a substitute for a glass globe, but he regarded paraffin balls as superior. In cutting a Thiersch graft he preferred a large flat knife with a blade an inch deep, the knife and skin being kept moist with sterilised normal saline irrigations. With regard to the wound to be grafted, all granulations should be completely removed, preferably with scissors, perfect hæmostasis being obtained by pressure. The wound could be washed when necessary with sterilised normal saline and kept immobile, covered with thin dry gauze dressing and cotton-wool, and left without interference for a week. At the end of that time the dressing should be removed by soaking it for the time necessary to float off the wool and the gauze, possibly as long as an hour.

In ordinary peace conditions the individuality of the patient should be taken into consideration in deciding on the procedure—i.e., his position in life, financial standing, and his occupation. In some cases the prospect of a long treatment and the repetition of operations with the inactivity had a bad effect on the mentality. Where there were no special circumstances limiting the choice of procedure, the method employed should be that which most nearly approached the normal.

Mr. T. P. KILNER showed a number of slides illustrating results secured at the hospital at Sidcup in cases of the kind under discussion. These included some very severe examples of symblepharon, in which Thiersch grafts were used successfully, both on the globe and on the inner aspect of the adherent eyelid. A further procedure carried out was that for replacing lost eyebrows. In dealing with a considerable number of cases of bad burns of the face, some of them by explosions of petrol, it was found that the eyebrows possessed three definite functions: shading the eye from the sun; acting as collectors of sweat—officers who had lost their eyebrows complained that when playing tennis the perspiration poured into their eyes; and the third function was protection of the eyes from the wind. Eyebrows might be made by whole-thickness grafts from hair-bearing skin, the area being carefully selected beforehand to see that the hairs were growing in the direction required in the brow.

Mr. G. H. POOLEY (Sheffield) said that, following the surgical removal of tumours, plastic operations could be carried out immediately if the base was satisfactory and the patient's condition warranted it. In the case of accidental wounds which were fairly clean, grafting could be carried out as soon as the wound became clean and quiet. But in the case of burns caused by molten metal, by chemical or by electrical means, grafting must be deferred until the contraction of the scar ceased. And where the deficiency of tissue was due to septic conditions, causing extensive sloughing, he considered that no attempt to graft should be made for at least 12 months after all sepsis had apparently ceased. When operating for any but recent injuries the skin should be incised about a quarter of an inch from the palpebral opening, parallel to the margin of the eyelid affected. It was most satisfactory, he found, to use a large flap with a wide pedicle, large enough to more than fill the space. For a badly contracted socket a modified long temporal skin flap could be used. The complication which he found caused perhaps the most trouble was that which following a burn produced an extensive adhesion of the eyelid to the eye, especially when a large part of the cornea was involved. For this, he divided a gross adhesion of the lower lid to the lower two-thirds of the cornea, and cut through the tissue which obliterated the lower fornix of the conjunctiva, cutting freely to each side, and continuing the incision below to three-quarters of an inch below the original bottom of the fornix. He then sutured a layer of rubber sheeting into the wound to keep the two raw edges apart. He left it in situ for months, until epithelium had grown over the raw surfaces. The result of this procedure had been most satisfactory.

Mr. J. J. SHAW (Edinburgh) showed a number of slides of cases on the screen, and described the operation he had carried out in each instance.

Mr. M. W. B. OLIVER adopted a similar method, and laid stress on the importance of not making the grafted lids bulky. A temporal flap should always include the superficial temporal artery. In order to carry out an epithelial inlay properly it was necessary to remove the whole of the conjunctiva and all the orbital tissue; his custom was to remove everything down to the periosteum. Moreover, the mould must be covered with one single skin-graft.

Mr. A. EDMUNDS gave his experiences with rodent ulcers of an extensive nature by means of grafts, his method of choice being to excise the growth and replace it by a sliding flap. He likewise showed a number of photographs of cases in stages.

Mr. T. HARRISON BUTLER said that in cutting Thiersch grafts it was an advantage to coat the razor with paroleine or sterilised olive oil.

Cases were shown before the discussion by Mr. MALCOLM HEPBURN, Mr. OLIVER, and Mr. F. A. WILLIAMSON-NOBLE.

MEDICAL SOCIETY OF LONDON.

AT a meeting of this Society, held on Nov. 9th, Sir HOLBURT WARING, the President, occupying the chair, a discussion on

OBSCURE PYREXIA IN CHILDHOOD

was opened by Dr. ROBERT HUTCHISON. Cases of fever in childhood without physical signs were, he said, met with in practice in three forms. The first were those with an acute fever which had lasted for more than a week without being accompanied by obvious physical signs; the second were those cases which had recurring bouts of fever; and the third had very prolonged fever but slight in degree.

Acute Fever without Signs.

In cases in the first of these classes influenza was apt to be the diagnosis arrived at, but in uncomplicated influenza the fever did not last more than a week, while if complications did exist, physical signs would be present also. An enteric infection should always be thought of, perhaps especially one of the paratyphoids, and this was not by any means excluded by the absence of all the classical signs and symptoms of paratyphoid infection. A diagnosis could be made in the early days by means of a blood culture, and, after the tenth day, by the agglutination test. Confirmation was afforded by the presence of leucopenia. A pulse-rate which was low in proportion to the temperature was always suggestive. Many cases in this same group were due to a pneumonia beginning deep down in the lung, or which affected only the apex, signs of which were either absent or had been overlooked. Also a high respiration-rate with "inverted rhythm" was suggestive, and light percussion would often, in such cases, elicit dullness. *B. coli* pyelitis in babies might produce an acute and sustained pyrexia, with but little to direct attention to the cause. The urine might seem clear, but a centrifugalised catheter specimen would disclose the organism; and the therapeutic test—disappearance of the fever when the urine had been rendered alkaline—would confirm the diagnosis. A very rare cause of obscure pyrexia in childhood was the condition known as medical septicæmia, but it might sometimes be found to follow an acute throat infection whose symptoms had been slight, perhaps had been quite overlooked. Rashes, joint pains, and other indications of a septic process might occur, and usually a blood culture would show the presence of streptococci.

A condition which should always be thought of in young children was acute otitis media. There might be but slight earache to direct attention to that organ, and inspection of the drum in young infants was often difficult. The problem might only be solved by the sudden appearance of a discharge from the ear. Dr. Hutchison was somewhat sceptical of teething being, in itself, a cause of continued obscure pyrexia, but admitted that occasionally cases were met with in which no other reason could be assigned. He quoted one or two such. Constipation might sometimes bring about even high and continued pyrexia, for it disappeared at once after a large enema. One child, 5 years of age, had, when seen, been running a temperature of 103° F. for eight days. The surroundings were insanitary, and at first it seemed likely to be enteric. But an enormous greenish offensive stool was evacuated, and thereafter the temperature became and remained normal.

Coming now to rarer causes of pyrexia, Dr. Hutchison mentioned first acute leukæmia. Especially if of the myeloid variety, this might reveal itself by fever for some days before enlargement of the spleen or glands, or the presence of anæmia were definitely perceptible. The possibility of acute miliary tuberculosis existing for some time, without definite evidence in the lungs or elsewhere, must always be present in the clinician's mind. A rapid respiration and pulse, and the presence of cyanosis, must be regarded as suspicious signs, and examination of the fundus oculi might reveal tubercles.

Recurrent Fever.

In the second group the child, usually beyond the age of infancy, had bouts of fever which lasted, at the most, for a few days, good health apparently prevailing between. Many of these cases were of alimentary origin, the so-called "food fever" of Eustace Smith, or the "hyperpyremia" of Francis Hare. These children, in many instances, had chronic intestinal indigestion or mucous disease, and the recurrence of the fever in them could be prevented by cutting down the diet, especially in the matter of milk, and by the administration of aperients and cholagogues. In another group of recurrent fevers the cause would be found to be a chronic septic infection of the tonsil. In these there would usually be a history at some time of acute tonsillitis, and the glands at the angle of the jaw would be found to be enlarged. Excision of the tonsils in these cases caused the attacks to cease. In children of about this age, too, chronic *Bacillus coli* infection of the kidneys, with periodic exacerbations, was an occasional cause of recurrent pyrexia, and could easily be overlooked. Examination of the urine during an attack would reveal the presence of the organism along with some pus. A focus of deep-seated tuberculosis, such as in the mediastinal glands, might also cause recurrent pyrexia. Methods of determining its presence needed consideration.

Prolonged Slight Fever.

In the third group the fever had lasted some weeks, even months, but was slight, perhaps not more than half or one degree in the evening. In some this was due to a chronic focus of sepsis, and the focus was very likely to be in the tonsils. Others were associated with chronic mucous colitis, which could be recognised by the presence of mucus and membranes in the stools. Latent rheumatism had sometimes been suggested as a cause of slight continued pyrexia, but the speaker considered that this was a rare event without other evidences of rheumatic infection, such as muscle and joint pains or chronic endocarditis. In this class of case, too, tuberculosis must be present to the mind, though that disease is not a frequent cause of this type of fever. Its exclusion from the possibilities was often a matter of difficulty. Teething could cause the same form of slight fever, and cases were adduced in which the fever ceased when a molar had been erupted. A further possibility which had been enlisted in this type of case was instability of the thermo-taxic mechanism, but the speaker's experience was that true neuro-mimetic fever did not occur in childhood. He suggested that the discussion might very usefully take the form of considering the means of excluding tuberculosis in cases of obscure pyrexia occurring in childhood.

Discussion.

Dr. WILFRED PEARSON said in some of the cases which had ended in an aural discharge the temperature had been of the septicæmic type, and the ear symptoms had been very slight. It was often an advantage to do a blood count, when a leucopenia and polymorphonuclear leucocytosis would sometimes be found. Deficient fluid might be a cause of fever, or the ingestion of sodium chloride might produce it. In dealing with cases of persistent slight temperature, the trouble often was in knowing what was the normal temperature to the particular child. His experience had been that up to the age of 10 years 99° F. must be regarded as normal in the morning, and in the evening 99·5°. In some slight temperature variations it was difficult to exclude a skin eruption, constipation, or slight catarrh. Sometimes a slightly high temperature was found to be a family characteristic. He agreed as to the importance of diagnosing between tuberculosis and mucous disease, but the differentiation had to be made mainly on clinical grounds. He had found much help from the fact that children with mucous disease wasted intermittently, while in tuberculosis the loss of weight was progressive and regular. It was also important to make a number of examinations of stools. It must always be remembered that tonsils which looked harmless might yet harbour a septic focus and keep up the temperature.

Prof. F. LANGMEAD agreed as to the frequency with which cases of *B. coli* infection were missed, largely because examination of the urine in a small child seemed so often to be regarded as of little importance, and specimens were not collected without difficulty. He had seen a lancing of the gums bring down temperature at once. One puzzling case was that of a child who was running a temperature of 104°, and eventually the administration of ergot brought away a dead round worm, and no fever occurred after that. The presence of intense cyanosis in a child should lead to strong suspicion that the temperature was caused by acute general miliary tuberculosis. Also there must be considered cases of "cyclical vomiting" without cyclical vomiting. He had watched some of these cases through and found that at about puberty they suffered from migraine. He referred to protein idiopathy as a cause of temperature in Dr. Hutchison's fourth group. In cases of long-continued bouts of fever it was important not to neglect the psychological background; some children exhibited fever following excitement, pain, or even excessive exercise. Tuberculosis might be the explanation of the fever in any of the groups Dr. Hutchison submitted, and he commented on the great discrepancy which existed between clinically diagnosed and undiagnosed (until autopsy) tubercle, a very important matter in such a serious disease. It was, however, on the whole, a disease which was well resisted by children.

Dr. **Walter Broadbent** spoke of the importance of the proximity of manholes as a cause of obscure pyrexia, and gave several examples bearing out his contention. He also showed that teething was a fairly frequent cause of pyrexia, which was stopped as soon as the gums were lanced. Sometimes tuberculosis following measles was a cause of temperature persisting, for a later sequel had been tuberculous meningitis. He also believed rheumatism to be a cause of intermittent pyrexia. He now treated his cases of rheumatic fever by placing them on the balcony in the open air.

Mr. E. D. **Davis** said that with regard to the tonsil, sometimes this was salient and obtrusive, but a deeply buried tonsil might be equally large. In an ear case the child was more obviously ill and looked ill. Examination of the child's ear with a Siegel's speculum obviated some of the disadvantages mentioned by Dr. Hutchison, and the comparative absence of pain in the ear was for the reason that there was not much tension at the site, and the child's drum would burst without much provocation. In children, otitis media sometimes developed very rapidly—within a few hours.

Mr. **Cecil Rowntree** said that the finding of calcified mesenteric glands indicated that those glands had at some time probably caused an obscure pyrexia, probably they were the kind of cases which had become infected in infancy with tuberculous milk, for infection from that cause frequently took place in the glands at the ileo-colic angle. Probably the trouble caused in early life was too slight to lead to a diagnosis. The X rays could be of use in the early stage of tuberculosis of mesenteric glands, as they showed a flocculent appearance; later the glands could be seen to be calcareous.

Dr. G. E. **Ward** gave an account of a striking case of pyrexia due to a round worm, the temperature at once subsiding when the worm was evacuated.

Dr. A. **Castellani** called attention to the group of parenteric fevers, with a behaviour like enteric. In Ceylon and India it was common to see children with fever whose stools were filled with acarus eggs. He referred also to ankylostomiasis fever, some cases of which exist, he said, in this country.

Dr. F. G. **Chandler** spoke chiefly on skiagraphic signs of tuberculosis in children, and exhibited skiagrams to illustrate his points.

Dr. G. W. **Goodhart** spoke on colon bacillus pyelitis as a cause of pyrexia, and questioned the opener as to the signs which were thought to establish the diagnosis. He would not himself lay stress on any of the organisms he might find in a child's urine.

Corrigenda.—In the Bradshaw lecture (The Lancet, Nov. 14th, p. 1010, col. 2, line 40) the phrase "their regular peristalsis" should read "the irregular peristalsis."

The word diuretin in the penultimate sentence of Dr. A. R. Gilchrist's article in the same issue on "Novasurol: a New Diuretic," should read *diuretic.*

GLASGOW ROYAL MEDICO-CHIRURGICAL SOCIETY.

A meeting of this Society was held on Oct 23rd, Prof **Archibald Young**, the President, in the chair, when a discussion took place on

Optic Neuritis and its Significance.

The President, introducing the discussion, referred to the varying applications of the term optic neuritis, and suggested a number of questions on which he hoped the discussion might throw some light He urged the importance of the early recognition of the presence of optic neuritis while the chances of saving vision were still reasonably good

Dr. H. **Wright Thomson** opened the discussion by reviewing briefly the terms in common use in connexion with inflammation or congestion of the optic nerve—e.g., retrobulbar optic neuritis, optic neuritis, papillitis, papillœdema or choked disc, neuro-retinitis, and optic pseudo-neuritis. He differentiated optic neuritis as seen by the ophthalmoscope in the light of recent pathology into two classes: (1) A true neuritis—i.e., an inflammation of the nerve head—to which the name papillitis was given. (2) Papillœdema, where the changes were due to œdema and histological evidence of inflammation was absent or so slight as to be negligible. Considering next the mechanism producing papillœdema, he quoted Sir John Herbert Parsons's views that the predominant factor was increased intracranial pressure, and referred to the three common theories as to its production. (*a*) Impediment to the return of lymph along the intravaginal space of the nerve. (*b*) Impediment to the venous return. (*c*) Arterial anæmia, leading to altered conditions of osmosis at the nerve head. While a true typical neuro-retinitis was easily distinguishable from a true papillœdema, there were many cases in which it was impossible to say whether the ophthalmoscopic picture was papillœdema or neuro-retinitis. Finally, Dr. Thomson referred to the extraordinary variation in the appearance of different persons' normal discs, and uttered a warning against the diagnosis of inflammation or œdema in the absence of any definite swelling or hæmorrhages, especially if both fundi showed the same picture.

Dr. A. J. **Ballantyne**, in discussing the part played by papillœdema in the diagnosis, prognosis, and treatment of medical and surgical cases, referred to some interesting figures obtained from the records of routine eye examination in (*a*) a general hospital, and (*b*) an eye hospital. In 1100 cases examined, without selection, in the wards of the general hospital, papillœdema was found in 5 per cent.; intracranial tumour, renal disease, and tuberculous meningitis providing the vast majority of examples. Among 6000 cases seen at the Eye Hospital only 0·5 per cent. showed papillœdema, and the majority belonged to two classes, renal neuro-retinitis and acute retrobulbar neuritis. In private practice papillœdema of any form or degree apart from albuminuric neuro-retinitis was extremely rare. In the Eye Hospital cases not a single example of choked disc or of intracranial tumour was found in over 6000 cases. Papillœdema occurred most frequently as part of a neuro-retinitis either frankly renal or arterio-sclerotic in type. Acute retrobulbar neuritis was surprisingly common, differing, however, from the classical description in that the cases presented a notable degree of papillœdema indistinguishable, in some cases, from that due to early cerebral tumour or from that of renal neuro-retinitis. Referring to the question of trauma as a cause of optic neuritis, the speaker quoted two cases in which papillœdema occurred, along with other evidence of injury to the base of the brain. This was attributed in the one case to œdema of the brain following concussion and in the other case to cavernous sinus thrombosis. Finally, discussing papillœdema as a guide to treatment, Dr. Ballantyne considered that it had little or no localising value in intracranial tumours, nor even was it a guide as to the side of the brain involved, and he concluded by making a plea for greater concentration on the simpler problem of decompression for the preservation of sight, rather than on the time-consuming though doubtless higher aim of the accurate localisation and removal of the tumour.

The following also spoke: Prof. T. K. **MONRO**, Prof. W. K. **HUNTER**, Dr. **BROWNLOW RIDDELL**, Mr. **DONALD DUFF**, and Dr. T. S. **BARRIE**.

The **PRESIDENT** then described briefly a method of supporting the bulging brain in extensive decompressive trephining, and showed a number of illustrative coloured drawings.

JAMES MACKENZIE INSTITUTE FOR CLINICAL RESEARCH, ST. ANDREWS.

AT a meeting of the Institute on Nov. 3rd Prof. **LORRAIN SMITH** read a paper on the Pathology of Focal Infection, illustrated by numerous lantern slides. The lecturer demonstrated the spread of infection from focus to focus in many infective conditions, including tubercle, and showed clearly that certain organisms could circulate in the blood without giving rise to noticeable symptoms, until they formed a focus in the tissues. These foci were found in connexion with lymph nodes which were exceedingly numerous in all tissues. On the settlement of an organism the local resistance might be sufficient to destroy it, but if the focus became established it acted as a centre of distribution from which other foci were formed. The main source of destruction of organisms was, however, undoubtedly the blood. The explanation commonly given of the formation of foci was the arrest of active material by mechanical obstruction in lymphatics or capillaries, but similar focal lesions resulted from the presence of soluble toxins in the blood. An investigation into the focal mechanism which was responsible for such results should advance greatly our knowledge of the liability to disease. The lecturer also drew attention to facts, established by Rosenow, suggesting that in some instances infective organisms might acquire a property by which they showed a selective preference for certain sites. Typhoid bacilli showed a noteworthy preference for the gall-bladder, for example, while metastatic infection in bronchiectasis showed a predilection for the central nervous system. The problem of general immunity had been widely investigated, but the question of local immunity and the focal mechanism upon which it was dependent had not been worked out. The paper gave rise to an interesting discussion.

BRISTOL MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held on Nov. 11th at the University of Bristol, when Dr. H. H. **CARLETON** read a paper on

Some Pulmonary Problems,

with a special reference to radiography. He emphasised three points in technique if the maximum value was to be obtained from skiagraphy: (1) rapid exposure, about half a second ; (2) the film must be sufficiently large to include the whole chest ; (3) a standard position for the target. In interpretation of skiagraphs, he said, it must be remembered that normal lungs differed widely in the amount of fibrous tissue they showed. Well-marked striation might be compatible with perfect health. Clinical fibrosis required dense shadows, falling-in and rigidity of chest, and shortness of breath. In silicosis the fibrous tissue often occurred in plaques. Peripheral stippling in intercostal spaces was seen alike in bronchopneumonia, tuberculosis, and silicosis. The differential diagnosis could not be made with certainty on radiographic appearances alone.

The mobility of the trachea led to visible deviation of the tracheal shadow in chronic cases. Such deviation was an index of chronicity, and therefore a measure of the powers of resistance on the part of the patient. Further deviation of the trachea and mediastinum was a guide as to the results of intrathoracic pressure in cases of pneumothorax, and, if noted, excessive pressures could be avoided. Fluid in the chest, when gas was also present (hydrothorax), presented a clean-cut mobile straight line, characteristic in appearance and widely different from the fine line seen in simple pleural effusion. It was impossible by skiagraphy alone to distinguish between the presence of serous effusions and pus in the chest. Glands in the chest did not necessarily indicate active disease; they more usually indicated good resistance. When stippling occurred in the intercostal spaces beyond the field of the intrapulmonary glands it was an indication that the glands had failed in their efforts to resist the advancing tide of infection. Cavities should never be diagnosed on X ray appearances alone without confirmatory clinical signs. Radiography showed that pulmonary tuberculosis was by no means so frequently an apical disease, even in its early stages, as was commonly supposed.

The speaker demonstrated the value of radiography in relation to treatment by artificial pneumothorax, both in the choice of cases and as a guide during the progress of induction of an artificial pneumothorax. He spoke of the possible dangers of infection of the pleura from the breaking down of adhesions, a misfortune which had occurred to him in a case of unilateral bronchiectasis. The lecturer expressed his thanks to Dr. F. J. A. Mayes and Dr. F. G. Bergin for their assistance in providing his series of skiagraphs.

Discussion.

Dr. **BERGIN** said that while agreeing that peribronchial infiltrations were usually not indications of tuberculosis, they were often indicative of early pathological changes. He did not agree that, if the upper level of fluid in a chest appeared as a line, gas was present.

Dr. **MAYES** maintained that an X ray diagnosis of tubercle could often be made before clinical signs enabled this to be done. He attached importance to diminution of diaphragmatic excursion ; this meant a gross lesion of the lung. He emphasised the importance to be given to shadows in the outer third of the chest area ; in the medial third shadows were not uncommon. The more dense and definite a shadow, the less active the condition causing it.

Dr. F. H. **EDGEWORTH** related a case in which good health was interrupted by a sudden hæmoptysis. No physical signs appeared, except loss of diaphragmatic movement, shown by X rays. Three weeks later an apical friction was found. Sanatorium treatment was successful.

Dr. J. O. **SYMES** thought that "skiagraphy showed too much rather than too little." He had never seen a case with no symptoms or physical signs in which the skiagram helped a diagnosis of phthisis. He was interested to learn of the tracheal deviation as a new and helpful sign, and asked whether there was any means of diagnosing adhesions by the X rays.

Mr. C. F. **WALTERS** related a case in which a definite upper level of fluid was seen. No empyema was found, but at operation a lung abscess was discovered.

Dr. J. A. **NIXON** said that screening was important. He agreed that striæ did not necessarily indicate tubercle, and that "cavities" diagnosed by skiagraphy often did not exist at autopsy. But a similar mistake was not unknown when physical signs were relied on.

Dr. **CAREY COOMBS** thought that a linear upper border of fluid did appear when no physical signs indicated gas, and suggested that we might have to reconstruct our ideas on intrathoracic physics ; this promised an interesting research. The great value of X rays lay in their help in showing the position and extent of lesions.

Reply.

Dr. CARLETON, in reply, said he thought there was one sign of a cavity which was reliable—a semicircular area of which the straight side was influenced by gravity, and which could be made circular by coughing up the contents. In regard to the line above fluid, he meant a clear-cut definite line, about which there was no mistake—this was pathognomonic of gas. When screening a chest the eyes should be fully accommodated to darkness; minimal illumination was useful in bringing out slight differences in transparence. Defective movement of the diaphragm was a sign of pleurisy, not of tubercle. He was satisfied that artificial pneumothorax was the best method of arresting hæmoptysis.

NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.

AT the first meeting of the session Mr. H. BELL TAWSE, the President, took the chair, and Sir STCLAIR THOMSON gave an address on Difficulties in Deglutition and Some Diseases of the Œsophagus. After strongly condemning the use of bougies, coin-catchers, and probangs, Sir StClair Thomson illustrated, by a series of lantern slides, the development of the endoscope from the time of Bozzini to the present day, and showed how the advent of electricity, cocaine, the telephone, the motor-car, and the X rays had made it possible for a patient having a foreign body in the upper air or food passages to be brought from a distance, diagnosed, and effectually treated within a few hours of the accident. Other slides showed congenital occlusion of the œsophagus, pharyngeal and œsophageal pouches, achalasia of the cardiac orifice, and malignant disease. The lecturer pointed out the futility of gastrostomy in congenital occlusion and the advisability of operating on pouches before the patient was too wasted. He asked philosophers to explain the thickening of the walls in achalasia; recommended early gastrostomy in malignant stricture; and, touching upon the difficulties and dangers of œsophagoscopy, drew special attention to the thinness of the œsophageal walls, and emphasised the need for the expert in these cases. He wound up his address by strenuously advocating the routine examination of the larynx and œsophagus in all cases of hoarseness or dysphagia of three weeks' duration.

ULSTER MEDICAL SOCIETY.

AT a meeting of this Society, held on Oct. 29th, Mr. JAMES A. CRAIG delivered his presidential address on the Retina in Constitutional Disease. After drawing attention to the close relationship between ophthalmology and general medicine, he spoke of the advantages of the eye as an organ in which to study the circulation and its abnormal conditions, and described Bailliart's method of estimating the tension of the retinal arteries. Having illustrated the ophthalmoscopic appearances in hyperpiesis and sclerosis, he laid emphasis on the part which sclerosis of the small vessels, such as those of the retina, plays in the production of general hypertension. An ophthalmoscopic examination afforded an index of the condition of the small arteries throughout the body. He pointed out how often sclerosis of the retinal vessels was discovered by the oculist in patients who considered themselves in perfect health, and discussed what should be done. Referring to the question how far the condition of the retinal vessels was a guide to that of the cerebral, Mr. Craig quoted the work of Foster Moore and Adams, and mentioned the parallel which exists between amaurosis fugax and retinal thrombosis, on the one hand, and temporary aphasia or paresis and cerebral thrombosis on the other. He then gave an analysis of 50 consecutive cases in which retinal hæmorrhages were discovered during a routine examination in patients complaining of eye symptoms. In referring to the unduly large percentage of these in which no information on the result of a general examination of the patient could be obtained, he appealed for a closer coöperation between the practitioner and the oculist. In a review of the subject of renal retinitis, attention was drawn to the resemblance which exists between the symptoms of eclampsia and those of acute lead poisoning. It was suggested that the constriction of the retinal vessels and blanching of the fundus characteristic of the latter might be found to some extent in patients suffering from eclampsia during the attack, although in this condition it was generally held that no changes occur in the fundus. The address concluded with a review of the evidence of the existence of diabetic retinitis as a distinct entity, and suggested a coördinated investigation by the oculist, physician, and biochemist, in order to add to the knowledge of the essential nature of the fundus changes associated with glycosuria.

FRENCH NATIONAL LEAGUE AGAINST VENEREAL DISEASE.

CONFERENCE ON CONGENITAL SYPHILIS.

THE conference on congenital syphilis organised by the League was held in Paris from Oct. 5th to 7th with Prof. Jeanselme in the chair, when the three days were devoted to discussion on (1) latent congenital syphilis, (2) the treatment of congenital syphilis in the suckling and the young child, and (3) the preventive treatment of congenital syphilis.[1]

Latent Congenital Syphilis.

Mr. Leredde opened with the assertion that alongside well-established cases of congenital syphilis with well-marked symptoms and signs and positive serum reactions, there exist much more frequent forms where the diagnosis is by presumption. Such presumption is permissible if there exist any congenital malformation or maldevelopment whatsoever, or any chronic malady in an infant the cause of which cannot be ascertained, any history in any relatives of any disease which may possibly be caused by syphilitic infection, any familial affection whatsoever, and certain varying changes in the blood and cerebro-spinal fluid. To the signs of congenital syphilis in young children described by Marfan, the speaker added cases of enteritis in the absence of any dietetic errors, eczema and prurigo in infants, and recurrent bronchitis in young children. Among the late symptoms due to latent congenital syphilis Mr. Leredde would include certain neuroses and neurasthenic states, epilepsy, mental deficiency, Parkinson's syndrome, incontinence of urine, "pure" mitral stenosis, emphysema, bronchitis, asthma, dyspepsia, chronic appendicitis, Graves's disease, and diabetes. He also stressed the close relationship between congenital syphilis and tuberculous infections.

MM. Lesné and Boutelier also brought forward a long list of disorders caused by latent congenital syphilis, and among others not mentioned by the previous speaker were Paget's disease, chorea, myopathies, and aerophagy.

Mr. Devraigne referred to Prof. Marfan's figures, which went to show that at the Hôpital des Enfants-Assistés 16 per cent. of infants had certain congenital syphilis, and if the probable cases be included this percentage is nearly doubled. He dealt with certain results of syphilitic infection on the fœtus and fœtal structures during pregnancy, and largely followed Marfan in his list of disorders in infancy due to syphilitic infection. He discussed the Wassermann reaction in congenital syphilis, pointing out that in the early months a positive reaction may be masked by, it has been suggested, the presence of excess of bile pigments in the blood.

---

[1] A full report of the discussion appears in the Presse Médicale, Nos. 82, 83, and 84, 1925.

Mr. Carle (Lyons) dealt with many of the masked forms of congenital syphilis, and among previously unmentioned diseases quoted infantile paralysis, disseminated sclerosis, mongolism, and many dermatoses. He emphasised the difficulty of diagnosis and said that he considered the result of antisyphilitic treatment the best criterion of the nature of doubtful signs and symptoms.

In the discussion which followed, Mr. Lesné uttered a note of warning lest any affection of childhood of unknown origin be called "masked" congenital syphilis, and dealt with certain diseases which are rarely caused by this but are more frequently due to other infections.

Treatment of the Newly Born.

Mr. Marcel Pinard dealt with the treatment of congenital syphilis after the birth of the child. He referred to the administration of mercury by the skin, by the mouth, and by the rectum, mentioning also the use by the mouth of stovarsol and treparsol. Intravenous medication, particularly the use of arsenical compounds, was thoroughly dealt with. He considered the intravenous route the most effective: it is less painful than the subcutaneous or intramuscular, the drug is rapidly absorbed and quickly arrests the syphilitic process. He thought that the use of too small doses might actually do harm.

Mr. H. Lemaire also considered the intravenous injection of novarsenobenzol the method of choice, and stated that accidents were very exceptional. He employs the drug dissolved in 4·7 per cent. glucose solution, and follows Marfan's dosage of 0·5 cg. per kilogramme of body-weight for a first dose, followed by 1 cg. for two doses, and then 1·5 cg. for the next five doses, all per kilogramme. The drug is given at weekly intervals for eight weeks. He referred to the use of bismuth by intramuscular injection, and considered that therapeutically mercury comes last on the list of these three drugs. The duration of treatment was generally about four years, although with novarsenobenzol this period might be somewhat reduced.

In the discussion which followed, Mr. Van der Valk, of Amsterdam, gave an interesting account of his treatment of 41 cases of congenital syphilis. He used calomel by the mouth and neosalvarsan by intramuscular injection over a period of three years. All symptoms disappeared, the infants put on weight in a regular manner, but with one exception the Wassermann reaction remained positive.

Preventive Treatment.

Mr. Milian divided his treatment into that given before marriage, after marriage, during pregnancy, and after pregnancy. He referred to the social questions involved, the question of the forbidding of marriage to infected individuals, and the examination of suspected persons. After marriage he emphasised that the best prophylaxis of congenital syphilis was the treatment of the woman before conception, and if pregnancy occurred, energetic treatment along accepted lines must be adopted at once. Even if the wife appears healthy and gives no indication of infection by a syphilitic husband, she should nevertheless be treated during pregnancy.

Subsequent speakers dealt with the question of professional secrecy where one parent is infected unknown to the other, to the fact that in a pregnant woman, undoubtedly infected with syphilis, the Wassermann reaction may be negative, and to the importance of widespread education on the whole question of venereal disease.

Reviews and Notices of Books.

NEUROLOGICAL FRAGMENTS.

By J. HUGHLINGS JACKSON, M.D., F.R.S., F.R.C.P. With Biographical Memoir by JAMES TAYLOR, M.D., F.R.C.P., and including the "Recollections" of the late Sir Jonathan Hutchinson and the late Dr. Charles Mercier. London: Humphrey Milford, Oxford University Press. 1925. Pp. 227. 12*s.* 6*d.*

To a younger generation of neurologists to whom Hughlings Jackson can only be a name, mentioned though it be with respect and affection by their seniors, this volume of reprinted Neurological Fragments will serve to indicate some of the grounds on which he is justly regarded as the pioneer of scientific neurology in England. The Fragments have been familiar to all those who learned from Jackson, and it is amazing how on a re-reading they still inform. They contain little that stands in need of modification. When a Victorian play is staged again to-day the critics are fond of pointing out how it "dates"; there is practically nothing in the Fragments that "dates," if by that is signified their containing points of view from which neurology has moved away. On the contrary, the principles they enunciate are in need of still further application.

It is pleasant, too, to have herein collected Dr. James Taylor's Memoir and Sir Jonathan Hutchinson's and Dr. Charles Mercier's Recollections. The hero-worshipper can never hear too much of his hero. Reading these intimate reminiscences, he will see again in his mind's eye the figure, and hear the soft accents, of the man who found English neurology insecure and shaky, and left it an edifice of marble.

OPHTHALMIC PLASTIC SURGERY.

Newer Methods of Ophthalmic Plastic Surgery. By EDMUND B. SPAETH, M.D., F.A.C.S., Chief, Eye Clinic, Walter Reed U.S. Army General Hospital, Washington. Philadelphia: P. Blakiston's Son and Co. 1925. With 168 illustrations. Pp. 258.

THIS volume embodies a good deal of experience in the treatment of facial deformities involving the eyelids, which were so painfully common in the war hospitals of recent years and are not unknown in civil life. This book was planned, we are told, to serve the general ophthalmologist in his everyday practice. It is, however, the reverse of elementary. The ordinary text-book methods of dealing with entropion, ectropion, ptosis, &c., are not given, only bare mention of them being made. The bulk of the text is devoted to those newer methods of plastic surgery to which so great an impetus was given by the war. Esser's and Gillies's methods of applying skin grafts, hair-bearing grafts for the restoration of lid margins, cartilage grafts for the restoration of the orbital floor, fascia lata and mucous membrane grafts, various forms of pedicle grafts for contracted sockets and for the reconstruction of either lid, these are samples of the subjects with which this book deals. The illustrations are copious and clear, but the text not always sufficiently explicit. Many of these procedures are difficult to perform and almost impossible fully to understand solely from explanations read in a book. The prudent surgeon, however, will not confine himself to a study of books as a preparation for this sort of work. In conjunction with practical experience this volume is calculated to be of great assistance to him.

A matter of some importance is that the author is decidedly opposed to the employment of paraffin injections in ophthalmic plastic surgery. The use of different substances to provide a movable stump after enucleation is discussed. The method preferred is employment of a glass ball in Tenon's capsule with careful suturing of the muscles. Dr. Spaeth has had but two failures in a series of 28 cases. He adds, however, a piece of information which will be new to many and ought to be known: "The life of a glass Mules's sphere in the orbit is between 20 and 25 years before the glass becomes eroded and breaks down." The work is completed by an appendix consisting of a classified bibliography in which the references which the author has selected as being most useful are given under various headings.

Diseases of the Heart.

Fourth edition. By Sir James Mackenzie, F.R.S., M.D., F.R.C.P., Director, St. Andrews Institute for Clinical Research; Consulting Physician to the London Hospital; Consulting Physician to the King in Scotland. London: Humphrey Milford, Oxford University Press. 1925. Pp. 496. 30*s.*

Sir James Mackenzie completed the fourth edition of his well-known text-book on diseases of the heart shortly before his death. The previous edition appeared in 1913, and in the intervening years the book has been reprinted with only a few minor alterations in the text. Largely as the result of the work of himself and his colleagues at the St. Andrews Institute for Clinical Research, the author felt that the time had now come to reconsider the whole conception of heart disease, and decided to incorporate his present view in a new edition of his previous work. In his later years Sir James Mackenzie had become firmly convinced that research in medicine, and especially in cardiology, had been diverted from the line most likely to lead to real progress, and was pursuing by-paths which resulted in the accumulation of a mass of facts that tended to confuse rather than to elucidate the central issue—namely, the mechanism of production of heart failure. He set himself, therefore, to seek out the fundamental conditions underlying ill-health and to formulate certain general laws based on these findings. He clearly states that the views put forward are not to be regarded as final, but merely as working hypotheses which will serve as a guide for future research.

In the opening chapters he discusses at length the mode of production of symptoms, and enunciates his theories of the principle of the reflex arc and the law of fluctuation in living tissues. The present edition, therefore, while retaining the essential features of its predecessor, notably the carefully considered opinions culled from the author's wide clinical experience as well as the illuminating account of his own epoch-making researches on the cardiac irregularities, contains much new matter of a more philosophical nature. The appearance of this new edition is a fitting monument to the remarkable energy which enabled its author to find time to carry out his scientific observations whilst engaged in a busy general practice, and even during his long illness to persist to the very end in his endeavour to advance medical knowledge.

Spirometry.

Vital Capacity of the Lungs. By J. A. Myers, M.S., Ph.D., M.D., Assistant Professor of Preventive Medicine and Public Health, Medical and Graduate Schools, University of Minnesota. With an introduction by S. Marx White, B.S., M.D., F.A.C.P. London: Baillière, Tindall and Cox; Baltimore: The Williams and Watkins Company. 1925. Pp. 140. 16*s.* 6*d.*

The author of this monograph on vital capacity claims to be on his guard against too enthusiastic an attitude to this subject, and yet he says: "The time is at hand when all persons should know their actual vital lung capacities, just as they should know their actual heights and weights," and goes on to suggest the instalment of spirometers in public places, very much like the familiar weighing machines. Apart from this lapse the book does succeed in giving a good and balanced account of vital capacity in its historical relations and in connexion with health and efficiency, and of its variations in disease. The name of Dreyer is associated with vital capacity in regard to physical standards and a good account of his work is given. Here it seems that there is a definite field for vital capacity estimations, but its use in diseases of the respiratory and cardiac systems seems to be very limited. It is rather surprising to find the statement that "probably the only help we receive from it is in differentiating pneumonia from certain other acute diseases" in a book whose preface claims that the vital capacity test is regarded by most clinicians as a "valuable aid in diagnosis, prognosis, and the guidance of treatment of certain diseases of the heart and lungs." The former statement appears to be nearer the truth. An extensive bibliography and numerous tables will prove useful to those interested in this subject, but even allowing for the large number of tables the price seems excessive.

The War Horse.

Official History of the War: Veterinary Services. Edited by Maj.-Gen. Sir Layton J. Blenkinsop, K.C.B., D.S.O., M.R.C.V.S., Colonel-Commandant, Royal Army Veterinary Corps; and Lieut.-Col. J. W. Rainey, C.B.E., M.R.C.V.S. London: H.M. Stationery Office. 1925. Pp. 782. £1 1*s.*

Each special department of the army has been allowed to publish officially its own account of the work done during the war; that of the Royal Army Veterinary Corps has now been issued. Veterinary science has advanced to such an extent during the past few years, and now has so many specialised branches, that it was necessary to entrust the compilation of the work to those who had specially studied the individual divisions, and the editorial work, owing to limited space, must have been difficult. It has been done so well that this volume will remain a useful work of reference and as a monument to the wonderful work of the Royal Army Veterinary Corps. The varieties of animals and the varied conditions under which they had to be kept and fed gave those in authority in the R.A.V.C. an infinite number of opportunities for exercising their ingenuity, and when it is considered that more than 75 per cent. of officers and men engaged in the veterinary care and treatment of the animals were civilians newly apprenticed to military methods, the results obtained were little short of marvellous. The book begins with a chapter on the preparations for war and mobilisation, and goes on to describe what was done on each of the numerous fronts for the welfare of the animals. No part of the world where the British forces were engaged is omitted, and the book shows clearly the difficulties which were overcome in the management of the healthy and sick horses in the extremes of heat and cold. All who served in the war, especially those who had animals under their charge, will find this book exceptionally interesting and valuable.

Royal Dental Hospital of London.

Annual Report for 1924. Edited by A. T. Pitts, D.S.O., L.R.C.P., M.R.C.S., L.D.S. London: John Bale, Sons and Danielsson, Ltd. Pp. 154. 7*s.*6*d.*

The Royal Dental Hospital's annual reports were originally issued under the joint editorship of Sir Frank Colyer and Mr. F. Coleman in 1910, but lapsed during the war and were only revived last year. No hospital or school news is now included, and the reports are in book form and contain original articles and case records only. In the present volume Mr. J. G. Turner gives a description of the minute anatomy of the roots of teeth. He regards the apical segment of the tooth and the dentinal canaliculi as the danger areas in root canal treatment, and rightly condemns so-called immediate root-filling after extirpating the tooth pulp. A certain time is required for the separation of living from dead tissues, and infected tissue is pent up if the root canal is immediately occluded.

Mr. Turner also describes two odontomes, one of which, a suppurating epithelial odontome (multilocular cystic disease of the jaw), was removed intact by the intra-oral route, showing that even large tumours may often be removed in this way and a disfiguring external scar avoided. Mr. W. H. Dolamore gives notes of three patients admitted to a general hospital for persistent hæmorrhage from the gums. In one of these patients, a hæmophilic boy, the hæmorrhage was arrested by means of protagulin; in the other two the bleeding occurred from the gums around the teeth, and the teeth involved were removed and the liberated gum margins approximated with suture with satisfactory results. Mr. E. F. Ackery and Mr. A. T. Pitts record six cases of acute stomatitis occurring in patients suffering from blood diseases, all of whom died. Their serious condition was recognised on their attendance at the dental hospital, and in every case they were recommended for admission to a general hospital. Mr. H. Stobie contributes a lucid and thoughtful paper on the diagnosis and treatment of some of the common tumours of the jaws. He lays stress on the value of radiology as an aid in determining the surgical technique to employ, and we are glad to see that the time-honoured text-book sign of eggshell crackling in connexion with the diagnosis of dental cysts has been omitted and resiliency (a more exact and expressive term) substituted. The use of a metal probe or, better still, fuse wire (as suggested by Mr. E. D. Davis) for passing into a cavity prior to an X ray examination might have been mentioned. If the latter be used it coils up within the cavity and serves to delineate its size and extent. We cannot agree that the swelling of cysts of the mandible is always limited to the outer alveolar plate, and the statement that "glandular enlargement and fixation" are early signs of an epithelioma needs qualification. Mr. Pitts writes on post-normal occlusion, a type of mal-occlusion that is receiving a great deal of attention from orthodontists at the present time. This condition appears to be more common than formerly, and it is difficult to say whether this is due to rapid evolutionary changes which are taking place, to failure in the past to recognise the condition, or to its confusion with superior protrusion. Mr. Pitts also discusses the pathology of the central myeloid sarcoma, the myeloid epulis, and the fibrous epulis, and questions whether the last is related to the other two tumours. Mr. D. M. Shaw discusses the value of "anatomical articulation," and endeavours to show that extensive contact of the teeth in all positions of occlusion does not exist in the normal dentition nor after marked attrition has taken place, and that it is not desirable that it should exist. His experiments show that different types of articulators elicit varying results of the mandibular excursions, and he considers that more care should be taken in observing the actual movements of the jaw, so that their effect can be reproduced in constructing artificial dentures.

The reports are a valuable and attractive contribution to oral and dental surgery.

Clinical Biochemistry.

By Ivan Maxwell, M.D., M.Sc., Lecturer in Physiology and Biochemistry, University of Melbourne. Melbourne: W. Ramsay. 1925. Pp. 124. 12*s.* 6*d.*

This volume is the companion to Osborne and Young's "Practical Biochemistry," of which the second edition was reviewed in The Lancet of Sept. 20th, 1924. It is intended to publish a third member of this series, and the author points out that any omissions will be included therein. Osborne and Young's small book undoubtedly started a new era in practical text-books of biochemistry, and it is to be hoped that the companion volumes will maintain this high standard. The present issue deals with the clinical aspect of practical biochemistry; like the first part, it is interleaved. Unfortunately, Dr. Maxwell's book does not show the careful preparation of the companion volume. The copy sent for review has many misprints which have been corrected in ink. We trust that all the copies have been so corrected, since some of the mistakes might lead to serious errors. The usual subjects are dealt with—renal efficiency, glycosuria, gastric analysis, and the tests of functional capacity of the various organs. The descriptions are rather sketchy in parts; the author is perhaps ill-advised in including a chapter on the enumeration of red blood corpuscles, &c., at the expense of the more purely chemical analysis of the blood. Clinical hæmatology is not a biochemical subject, and the space allotted could well have been used to describe methods of air analysis and respiration, a branch not even mentioned in the book. The method of determining the blood-urea is described, but the non-protein nitrogen of the blood is not even mentioned. In the method chosen for the estimation of urinary diastase no account is taken of hydrogen-ion concentration. Insulin is simply mentioned by name, and no account of the various clinical biochemical tests associated with insulin therapy is given. On the other hand, the book has certain excellent qualities. The general arrangement is very good, and the descriptions are all quite clear. Undoubtedly the best chapter is that upon hepatic efficiency; here an admirable account of recent work is given, and in particular of the Van den Bergh reaction. If in the third volume of this series are included exact details of quantitative analysis, the whole should prove of great value. Dr. Maxwell's contribution is in itself a useful addition to biochemical literature.

La Pratique Chirurgicale Illustrée.

By Victor Pauchet. Vol. VII. Paris: Gaston Doin. 1925. Pp. 250. Fr.30.

The English translations of the six earlier volumes of this work have been reviewed in our columns. This one is compiled on the same lines. The non-operative treatment of fractures of the upper extremity forms an interesting section and is well worth perusal, though some of the apparatus used appears a little heavy. The removal of cancer of the thyroid is depicted by a series of drawings made from a difficult and extensive case. A considerable part of the book is concerned with gastric surgery. Most interesting is the account of carcinoma of the stomach. The author prefers a one-stage excision, but says that sometimes he is forced to a two-stage operation. There is some discrepancy in the statements on this question; on one page the two-stage operation is said to have many advantages, whilst on another all patients operated upon in this manner are said to be dead within a year. The author still employs the Murphy button in some gastric operations. An ingenious technique for staphylorrhaphy is described by Victor Veau. Virenque brings forward a procedure for the removal of facial wrinkles not likely to become popular in this country. The illustrations are unusually clear and suggest a marvellous agility in the surgeon who performed the operations from which they were drawn.

Operative Cystoscopy.

By E. Canny Ryall, F.R.C.S., Founder of, and Senior Surgeon to, All Saints' Hospital for Genito-urinary Diseases. London: Henry Kimpton. 1925. 70*s.*

This is a superb atlas of operating cystoscopy comprising 115 plates, nearly every one of which has six coloured cystoscopic views. Every conceivable phase of intravesical or urethral manipulation is described. The author must have had an immense experience to have obtained views of so many different conditions, and they have been portrayed by Mr. Thornton Shiells with a faithfulness to nature unsurpassed by any cystoscopic atlas emanating from abroad. Mr. Ryall has extended operative methods through the cystoscope to what must surely be near the limit and has modified most of the usual instruments to render his methods more easy of execution. A unique feature is that the descriptions appear in German and French as well as English. There is an all too short account of methods at the beginning of the book, which renders the reader eager for more information as to what are the end-results of intravesical operations and in what percentage of cases such treatment is suitable. The author must have made a great number of observations and have case-histories at his disposal bearing on these questions. We hope he may in the future be induced to commit them to paper.

THE MAYO CLINIC.

Collected Papers of the Mayo Clinic and the Mayo Foundation. Edited by Mrs. M. H. MELLISH. Vol. XVI. 1924 (published May, 1925). London and Philadelphia: W. B. Saunders Company, Ltd. Illustrated. Pp. 1331. 60*s.*

THE Mayo Clinic and the Mayo Foundation have, in this sixteenth issue of their annual volume, maintained their usual standard of interest. The book is a bulky one and contains 222 papers or abstracts of papers from the pens of 160 contributors, many of whom have achieved world-wide reputations. As is inevitable, some of the contributions are of ephemeral interest and a few were frankly not worth reprinting, but, taken as a whole, the volume gives an excellent view of the march of surgery during 1924. In general, the papers are brief, so that the collection of articles on a subject such as gastric and duodenal ulcer forms an interesting symposium within a reasonable space. Another group of papers of particular interest is that concerning the physiology and diseases of the gall-bladder. The systematic recording of cases has evidently been brought to a fine art by the Mayo Clinic, and the results of this are to be seen in several articles such as that on diverticulitis of the colon, in which are summed up observations on this condition made during the last 17 years. A large number of addresses of a more general nature appear under the names of the founders of the Clinic. The 11 pages occupied by W. T. Mayo's lecture on the Physiology and Pathology of the Blood in Relation to Surgery are packed with learning and wisdom, and demonstrate that the work of the Clinic is not likely to be marred by any narrowness of outlook. The volume appears to have been very well edited, and rare errors, such as a reference to "hydro-arthritis or glutton's joints," on p. 664, give no annoyance.

JOURNALS.

BRITISH JOURNAL OF OPHTHALMOLOGY. September–October, 1925.—To the September issue H. M. Traquair contributes a paper on Acute Retrobulbar Neuritis affecting the Optic Chiasma and Tract. This is a little-known condition. Attention was first drawn to it in 1912 by Roenne who tabulated ten cases, five of them personally observed. In the present paper the author gives notes of four new cases, one of them already published by himself in a series of papers in the first volume of the *British Journal of Ophthalmology* (1917) under the title Bitemporal Hemianopia, and at that time believed by him to be caused by abscess of the antrum. He now regards this particular case as one of a class which Roenne describes as "inflammatory or degenerative conditions which have their starting-point in the chiasma or tract, and form a group of certainly existing but little known primary lesions in this part of the visual path." He suggests that if exhaustive analysis of the field defects in cases of retrobulbar neuritis were more commonly practised cases of this type would be more frequently found than they are at present. As in retrobulbar neuritis of the usual type, the prognosis as regards recovery of sight appears to be excellent, but should be guarded in respect of later development of nervous disease.—D. J. Wood gives an account of two cases of non-traumatic cysts of the anterior chamber and R. E. Wright a cyst of the iris. These two notes describe a condition which is decidedly rare and the pathology of which is not completely understood. This number contains a condensed report of the proceedings of the convention of English-speaking Ophthalmological Societies held in London in July.——The October number opens with a biography of Sir William Bowman by R. R. James. The value of a paper by Miss Ida Mann on the Development of the Human Iris, which occupies the chief part of the issue, is much enhanced by copious and clear figures. Among other papers is one by H. Hartridge on Helmholtz's Theory of Accommodation. This should be read in connexion with an abstract by C. Goulden (in the same number) of E. F. Fincham's paper, the Changes in the Form of the Crystalline Lens in Accommodation.[1] By means of careful measurements taken with the help of the corneal microscope and slit-lamp Fincham finds that the general truth of the theory of Helmholtz is confirmed. The increase in the curvature of the lens surface, however, does not in all cases correspond to the increase in accommodation. The factor accounting for these variations Fincham finds in the combination of the elastic nature and the varying thickness of the lens capsule. H. Hartridge, in his paper, supports Fincham's views upholding the theory of Helmholtz in opposition to that of Tscherning.

INTERNATIONAL MALARIA CONGRESS.

THE First International Malaria Congress was held in Rome in the Exhibition Palace from Oct. 3rd to 6th. The various delegates, some representing governments or societies, were welcomed by Senator Ettore Marchiafava, the President, accompanied by various members of the executive.

Signor H. E. Benito Mussolini, Prime Minister of Italy, who officially opened the Congress, stated that the Italian Government had a great interest in this gathering in Rome. He referred to the epoch-making researches, which had led to our full knowledge of malaria, as a striking example of international coöperation, but admitted that the practical problems of prevention remained.

Senator Marchiafava, in his address to the Assembly, showed how the old Latin views on malaria approached and harmonised with modern concepts.

Biology of Malaria Parasites.

Prof. Marchoux (Pasteur Institute, Paris), who brought the greetings of France and her doctors, read a paper at the first meeting of the Congress on Unity or Plurality of the Parasites, dealing in turn with the arguments provided by the two schools of thought. The former, led by Laveran, had been impressed with the differences found in the parasites seen in the blood of Europeans infected in the tropics, containing small rings and crescents when abroad, but when they relapsed at home, showing only the large amœboid forms such as were regularly found in the blood of autochthones. The pluralists, including most malariologists, based their views largely on experimental observations, and interpreted the above findings in a different manner. In the mosquito the zygotes were different, the time of evolution varied, and if fed on carriers of one form, the same type was invariably transmitted to healthy subjects; similarly, injection of infected blood, now repeated thousands of times, followed the same rule. Culture in vitro had so far revealed specificity.

In the discussion which followed Prof. P. Muhlens (Hamburg) said that his own inoculation work, in general paralysis, confirmed an immutability in the transmission of all types, whatever the period of the year, and even in Germany in winter 70 transmissions of benign tertian had been made without change.

Prof. Swellengrebel (Amsterdam) referred to experiments he had conducted in Sumatra with *A. sinensis* and *A. ludlowi*, demonstrating a difficulty which might arise in cases of mixed infection and might lead to the erroneous view that a transformation of type had occurred.

---

[1] Trans. Optical Society, 1924–25, vol. xxvi., No. 5.

Malaria Therapy in Psychiatry.

Prof. Auguste Marie (Paris) read a paper on this subject, in which he dealt with the thermic and visceral reactions, the precautions to be taken as to choice of case and the necessary blood controls when using malaria, and referred to the use of quinine and stovarsal—the former seeming to produce destruction of young asexual forms in the blood, whereas the latter rapidly affected the adult schizonts and the gametes. The results published in many countries, he said, showed that many thousands of cases had been treated and followed up, and whilst general paralysis of the insane was not cured by this form of therapy, it was proved that stabilisation took place with such persistent remissions that readaptation to family life and to social responsibilities were possible.

Colonel S. P. James (Great Britain) said that in England it had been found by experience that the relatives of patients objected to the direct inoculation of blood from paralytics, knowing that such were syphilitic, and that they feared what were called "neurotropic strains" of the virus. Also, by the use of the blood method the risk of injecting two kinds of parasites at the same time could never be completely eliminated. For these reasons it had been decided to inoculate only by means of mosquitoes; stocks of infected anopheles were kept for the purpose and distributed to those who needed them. The results by the natural method had been carefully observed in over 100 cases and were held to be better than when the blood method was employed.

Prof. M. Ghiron (Rome) read a communication on certain points of interest revealed during inoculations of general paralytics with malaria. Several months after the injection of subtertian he had reinjected some cases with benign tertian and found that a marked resistance had developed; not only was the hæmoclasis absent, as compared with controls which had not previously received subtertian, but there was no febrile reaction.

Anopheles and Malaria.

Dr. Massimo Sella gave a report on a new method for mosquito control in Italy by the acclimatisation of the larvi-phagous fish *Gambusia holbrooki grd.* He said that *complete* control of mosquito breeding could be obtained, even in drainage canals, provided there was thorough removal of surface vegetation; also, that great saving had been effected as petroleum was no longer required in some regions. Dr. Sella developed the theme of more intensive cultivation and distribution, and the need of special organisations, legal and financial support in this new method.

Dr. Etienne Sergent advocated all practical means of controlling malaria, from flight from the danger to disciplined control of those living in infected zones. He valued prophylactic quinine to keep people at their employment; he placed more stress on treatment and cure by quinine as a direct measure, and on all indirect measures based on propaganda work, first and chiefly amongst the children, and constant illumination of public opinion.

Colonel James said that the Malaria Commission of the League of Nations Health Committee had recommended: (1) the treatment of all cases as the first problem; (2) that it was not wise to use quinine as a prophylactic; (3) the killing of adult anopheles in houses; (4) that antilarval measures must have a very secondary place.

Larvicides.

Dr. M. A. Barber (U.S. Public Health Service) reviewed his work on Paris Green as a Larvicide. This arsenical poison was now widely used through the United States, and had been successfully employed in Palestine and Italy. It might be used through the entire season without harmful effects, had not been shown to affect animals or fish, and was employed diluted with 100 parts of dust as a suitable vehicle for wind conveyance over marshy areas covered with dense vegetation. Being almost insoluble in water, the light particles were held up on the surface-tension layer, and remained long enough to poison all surface-feeding larvæ.

Dr. L. W. Hackett (Rockefeller Foundation, Italy) issued a warning as to the varying qualities of Paris or Schweinfürth green on the market; some, he said, were merely aniline products. The U.S. Government had introduced a legal standard that Paris green must contain 50 per cent. of arsenious oxide.

The Alkaloids of Cinchona and Malarial Therapy.

Dr. A. Kaufmann (Switzerland), in a paper on the Synthesis of Cinchona Alkaloids, said that research was now so far advanced that the coöperation of the pharmacologist and clinician was needed by the chemist to test the pharmacodynamics of every product.

Colonel James and Dr. H. H. Dale, F.R.S., made a communication on the Relative Therapeutic Efficacy of Quinine, Quinidine and Cinchonine in Malaria. New tests had been made, using pure products, to determine the immediate therapeutic effect—i.e., the time required for complete disappearance of parasites from the blood. Results so far obtained showed that the curative effects of the three alkaloids was the same for all forms of malaria; in small doses cinchonine was slightly less effective than the others; there was no difference in toxicity save that quinidine had a more marked depressant action on the heart muscle.

Resolution.

An important communication was read by Dr. Fernando Perez, Argentine Minister in Italy, who proposed that in order to complete and consolidate the work of the Congress a permanent International Malaria Institute should be created in Rome with the scientific and financial help of all nations.

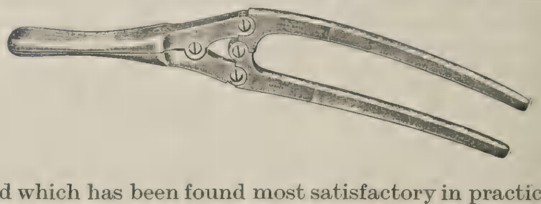
The President replied that the Italian Government viewed with favour the creation of such an organisation; it had great sympathy with the project, and was ready to give its moral and material support to this new institution.

The proposition was greeted with acclamation, and was subsequently adopted by the Council of the Congress, who formally expressed the desire that the Italian Government should make itself the mouthpiece of this wish to the Governments concerned in order to enable the project to be realised.

New Inventions.

INTESTINAL CLAMP.

In performing resection of the intestine, it is advisable to have a powerful clamp to crush the bowel before it is divided. The illustration shows a clamp which I have been using for the past 12 years, and which has been found most satisfactory in practice. The features of the clamp are: (1) its simplicity, (2) its power, (3) the area of bowel crushed is sufficiently wide to allow of the application of two ligatures between which the bowel is divided with a cautery. The clamp has been made for me by Messrs. Down Bros., Ltd., who have carried out my suggestion in their customary efficient manner.



HERBERT J. PATERSON, C.B.E., M.B.,
London, W. M.Ch. Camb., F.R.C.S. Eng.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 21, 1925.

THE SCHOOL MEDICAL SERVICE.

THE compulsory Education Acts have had two great effects. They have provided for every child a certain amount of learning at the price of reduced parental responsibility and freedom, and they have placed that child partially in the care of the State at a critical stage of physical development. The educational authorities aim at increasing the mental equipment of the pupils; the School Medical Service tries to increase their health and remove any causes of disease which may arise in the course of schooling. Whilst education may or may not be invariably beneficial, a betterment of children's health is wholly desirable. There is but one danger in a little physical betterment, and that is that it may be regarded as sufficient. At a small sacrifice of individualism there has been forged against disease a weapon whose power is incalculable, and there must be no resting on past achievements until that weapon is given full play. Sir GEORGE NEWMAN's report to the Board of Education on the Health of the School Child,[1] shows a proper appreciation of the admirable work that has been done in the past and reflects the still more proper discontent which animates the School Medical Service to-day. It contains lessons which must be learnt by the public at large and by public authorities in particular. The magnitude of the work is shown by the fact that in 1924 the average number of children attending schools under Local Education Authorities exceeded five million. The requirements of the regulations were fully met by the 1884 part-time or whole-time medical officers employed, and 2,420,000 children were medically inspected—that is to say, 48·6 per cent. of those who attended school during the year were examined. Of these about 700,000 were seen on account of some special illness or defect; of the remaining 1,660,000 who came up for routine examination, 19·8 per cent. were found to be suffering from some more or less serious physical defect which needed treatment then and there. In addition a considerable group, amounting to some 108,000 children, were found to suffer from physical or mental defects such as blindness, deafness, epilepsy, feeble-mindedness, tuberculosis, and crippling. For these children there were 544 special schools and sanatoriums accommodating over 43,000.

It has sometimes been objected that the routine work of inspection and compiling statistics is a waste of time. Sir GEORGE NEWMAN points out, however, that the routine work involved in the medical inspection of *all* children, healthy or sick, at certain prescribed stages of their school life is one of the fundamental principles of the whole enterprise. Nothing but chaos and waste, he believes, would ensue if this inquest of the nation's children were drifted through, in haphazard fashion, without record or report. The report before us is sufficient evidence of its own usefulness. Nor, to our readers at least, will any criticism of the time and labour and expense devoted to research need an answer, though Sir GEORGE NEWMAN supplies cogent ones. An example of the kind of research being carried on is the special investigation into the health of the rural child which was made in the spring of this year. This revealed much that needs reform in the incidentals of rural education and many regrettable results of poverty amongst the children of labourers and those in casual employment. Although it was found that there is no widespread decadence, and that on the whole there is probably improvement, it is clear that the remarkable progress in physical well-being which has taken place in the towns is not shared equally in the rural districts, and there is a substantial degree of impairment amongst rural children, especially at the ages of 6 to 12 years. On the whole, the country children are still ahead of the town children, but in some areas they are falling behind. Sir GEORGE NEWMAN's general conclusion is that although every year there appears to be the same tide of disease, the same burden of defect requiring treatment, there is undoubtedly a great and almost universal improvement in the *degree* of disease among children of school age. The death-rate at these ages is declining, and the gross forms of disease are steadily disappearing. "Medical care," it is stated, "has brought about an immense improvement in the discovery and practical treatment of the defective child, and thus has mended the particular child and stopped the evil effects of disease. But concurrently there has been little or no change in the causes and origin of disease in school-children . . . The young child comes to school already diseased. In 1924 38 per cent. of the entrants in London were found to require medical treatment . . . This clearly is home-produced and not school-produced. But, further, there is evidence that the physique of a number of children degenerates *while they are at school*." In a recent summary of school medical work [2] we drew attention to the deplorable hygienic conditions to be found in some schools. Lack of facilities for washing, inadequate lavatory equipment, and general uncleanliness were condemned as prejudicial to health and stultifying of that instruction in personal hygiene which should be an essential part of school medical education. We drew attention to the fact that in many schools children remained all day in the wet clothes and boots in which they arrived, and to the meagre floor space allotted to schools by regulations unchanged since 1870. It is satisfactory to find most of these abuses the subject of earnest recommendation to local authorities, though it is regrettable that such recommendation should still be needed.

There is an increasing desire on the part of parents to take advantage of treatment offered; but there remains a considerable leakage between the number of children requiring treatment and those who actually get it. More, it is suggested, might be done by many authorities to follow up, to make treatment available, and to prescribe the duties of their medical staff in such a way as to make it possible for them to concentrate on the untreated child. In many areas the personnel of the School Medical Service is too small to conduct anything more than the barest routine. The number of dentists is wholly insufficient. Of 1,766,000 children inspected by them in 1924, 67 per cent. were found in need of immediate treatment; but only 55 per cent. of these received it. It is stated that to establish a complete dental service for all school-children the number of dentists employed would require, at the lowest estimate, to be trebled.

---

[1] The Health of the School Child. Annual Report of the Chief Medical Officer to the Board of Education for the Year 1924. London: H.M. Stationery Office. 1925. 1*s.* 9*d.*

[2] THE LANCET, 1924, i., 44.

The whole trend of medicine to-day is towards treating the underlying causes of disease rather than the symptoms. Certain established causes such as focal sepsis act early and are susceptible to rational treatment in infancy and childhood. From the barest commercial point of view, then, it ought to be possible to devote more than £1,220,000 a year to the work of the School Medical Service.

CONGENITAL SYPHILIS.

Perhaps one of the things which most attracts the notice of a British visitor to the children's hospitals of Paris is the frequency with which the diagnosis of congenital syphilis is made on what appear to be insufficient grounds. The recent conference on congenital syphilis in Paris, of which we give an account elsewhere in this issue (p. 1071), also brings out this striking difference between the points of view of two sets of pædiatricians. The list of diseases attributed to latent congenital syphilis includes such affections as chorea, mitral stenosis, exophthalmic goitre, and infantile paralysis, and greatly exceeds both in quality and quantity the result of experience in this country. It may be that congenital syphilis is a much more common disease in France than it is in this country, and there are certain statistics to bear out this contention. Prof. Marfan's figures, collected, it is true, in a sort of Poor-law institution where many illegitimate children are presumably to be found, go to show that 16 per cent. of all infants are definitely infected, while about 30 per cent. are probably so. In this country, on the other hand, figures collected by Dr. G. F. Still show that not more than 1 per cent. of all out-patients in a big children's department are suffering from congenital syphilis, as judged on clinical grounds alone, and he further quotes the results of the Wassermann reaction in the blood of young infants in an investigation in the East End of London where only 4 out of 677 cases were positive. Even this striking statistical difference will not, however, account for many of the views held by French authorities. Prof. Marfan's teaching on rickets, for example, is to the effect that the large majority of cases are due to congenital syphilis, and the difficulty arising with regard to negative Wassermann reactions in many of these cases of so-called masked congenital syphilis is met by the statement that the biliary pigment in the blood of new-born babies interferes with the hæmolysis involved in the test. Another somewhat dangerous point of view brought forward in support of the latent congenital syphilis theory is the fact that many of these cases respond to antisyphilitic treatment. This post hoc line of argument may be particularly misleading in dealing with a vague and heterogeneous group of chronic infections in which almost any therapeutic measure may at times secure a striking success.

On the subject of the treatment of congenital syphilis there is in general more agreement, although in the course of the discussion on this aspect of the problem there was a distinct tendency to give first position to the intravenous use of arsenical preparations and to place mercury as a rather poor third in the list—arsenic, bismuth, mercury. In this respect a recent publication of the results of the treatment of congenital syphilis in this country by Mr. John Adams is particularly interesting.[1] He has treated since 1917 164 consecutive cases in young babies at the Thavies Inn Clinic for pregnant women suffering from venereal disease. The mother's blood is examined on admission and treatment instituted at once if the pregnancy has not yet terminated. As soon as the child is born a specimen of blood is taken from the umbilical cord and also from the mother and sent for a Wassermann reaction to be performed. It was found that about 3 per cent. of pregnant women, although undoubtedly suffering from syphilis, gave a negative Wassermann reaction, and of the babies born of syphilitic mothers this reaction was positive in 51 out of 152 cases. The treatment adopted has been the intramuscular injection of galyl in glucose, commencing on the first day with 1·25 cg. and working up to 3·5 cg. in fortnightly doses. Altogether nine doses are given, the second one at the end of the first week. Combined with this are intramuscular injections of mercury in doses of $\frac{1}{6}$ gr. working up to $\frac{1}{3}$ gr. at fortnightly intervals and grey powder by the mouth. At the ninth and twelfth months courses of three injections of 3–5 cg. of galyl are given, and 1 gr. of grey powder daily for a month and repeated at the eighteenth month. Further treatment is governed by the progress of the case. During the last five years not one baby born alive has died in the hospital, and there have been altogether only four deaths in the whole period of eight years, while in the last few years there has been no still-born fœtus in the clinic. The effect of the treatment is to convert a positive Wassermann reaction in the infant into a negative one in an average period of 10 to 11 weeks; this has occurred in every case, a striking contrast to continental experience and to the reports of other workers in this country. Babies thus treated grow up into strong, healthy children with a mortality-rate actually below the normal for non-syphilitic children. Mr. Adams utters a word of warning against puncturing the superior longitudinal sinus for obtaining blood, and describes a very satisfactory method for getting it from the heel. His experience is that congenital syphilis, like syphilis in general, is becoming less frequent in this country.

CIVILISATION AND BLOOD PRESSURE.

High blood pressure is a subject of wide and perennial interest—an interest justified by the obscurity which still surrounds the condition. Speaking before the Academy of Medicine of Toronto on Oct. 12th, Lord Dawson of Penn referred to high blood pressure as an apparently increasing result of modern civilisation. Apart from nephritis, he considers the blame should fall on faulty metabolism, on anxiety, and perhaps on inborn traits. About the age of 46 a jump in blood pressure from 120 to 140 is not uncommon, and although raised pressure is not rare in thin people, the man who becomes too fat in middle life is most open to suspicion. At this age a general loss of flexibility may begin to show itself, and what Lord Dawson aptly called "a certain fibrositis of the mentality." How far a rise of arterial tension depends at first on circumstances is illustrated by a case which he cited of a barrister in whom the blood pressure was in two successive years reduced by the annual holiday from 140 to 120, but who failed to respond on the third occasion. It is, says Lord Dawson, the anticipation of work that plays so important a part at certain ages, especially in those who show a general vasomotor excitability and lack of adaptability. That such a predisposition exists was shown in an examination of 1500 students at the University of California, of whom fully 20 per cent. had high blood pressure. A similar examination was made by Lord DAWSON and others in four English schools, when it was found that 8 per cent. of the 659 children between the ages of 11 and 17 showed too high pressure, though the affected children appeared as healthy as the others. The group in which it occurred was one in which the boys and girls of almost 17 years of age were trying to pass examinations on which much depended, either for themselves or their parents. Many of them had a blood pressure of over 130 and in some it reached 150. Here the influence of anxiety was obvious.

[1] Ante-natal and Post-natal Syphilis. By John Adams, F.R.C.S. London: John Murray. 1925. For private circulation. See also The Lancet, 1920, ii., 990, 999.

The American view of the importance of a small rise in arterial tension is illustrated by a somewhat popular treatise written by Dr. W. E. SADLER, of Chicago, and entitled "Americanitis."[1] It is clear that in the United States a man with a blood pressure of over 140 is looked at askance. Lord DAWSON does not go as far as to share the view there prevailing; but he states that a youth with this degree of tension should endeavour to find a salaried appointment. Whole families may show an increased blood pressure, and there may be no obvious results because work and surroundings are favourable. A great deal of the world's most important work is, in fact, done by those who suffer from hyperpiesis and it would be easy to exaggerate the alarming nature of small rises; their disastrous sequels have yet to be shown. Twenty years ago persons applying for life assurance policies commonly found themselves heavily loaded on account of the readings of the sphygmomanometer; yet we are informed that many experienced physicians to-day have records of continuous good health in such people, who have endured their high blood pressure without symptoms or obvious ill-effects. It is well known that the outlook is grave in cases with marked elevation of both systolic and diastolic pressure; but the importance of a pressure of 140 mm. in otherwise healthy young people cannot be estimated accurately yet. It often shows a state of mind and body which demands consideration of appropriate environment and work; but until full records have been obtained which clearly show some relation between moderate juvenile high blood pressure and early death, judgment may be reserved, and it seems undesirable to penalise or alarm those in whom such a condition is discovered.

LEAGUE OF NATIONS: MEMORIAL PRIZES FOR THE STUDY OF MALARIA.—In memory of Dr. Norman Lothian (see THE LANCET, 1925, i., 1159) and Dr. Samuel Darling (ibid., 1925, i., 1320), the two members of the Malaria Commission of the League of Nations who were killed in a motor accident near Beyrouth on May 21st, 1925, while investigating malaria conditions in Syria, the League's Health Committee has decided to create a Lothian Scholarship and a Darling Prize, which will be awarded periodically for the encouragement of malariological study. The Lothian Scholarship, for which a credit has been found in the budget of the Health Organisation of the League, will be awarded by the Malaria Commission to a selected candidate "whose course of study should be in conformity with the general programme of the Malaria Commission," while the Darling Prize (a medal or other reward) will be given to the scientist who "has carried out recent distinguished research work on a subject connected with malaria which comes within the general scope of the Commission's investigations." The funds for the latter foundation will be raised by private subscription.

Annotations.

"Ne quid nimis."

THE DENTAL BOARD.

IN his address at the opening of the ninth session of the Dental Board of the United Kingdom on Nov. 10th Mr. F. D. Acland, the chairman, dealt with three matters of considerable importance to the welfare of the dental profession. With regard to advertising, he said that very considerable progress had been made in carrying out the Board's duty of checking undesirable methods of announcing a dentist's practice. It was not only interesting but gratifying to find how willing practitioners were to conform to the wishes of the Board; the only proviso made was that all dentists should be on the same footing. This, of course, is reasonable, and the Board is endeavouring to ensure that all are treated alike, though naturally it is difficult to enforce exact uniformity and simultaneity of action. Some practitioners, he continued, desired that the Board should lay down hard-and-fast rules to which all should conform. There was much to be said on both sides. In a professional district and in a crowded shopping street, the question arose whether it would be possible to give sufficient definition of the difference in situation of premises as would at the same time afford a clear guide to dentists, and prevent the occurrence of numerous and difficult border-line cases on which the Board would have to make special decisions. Some of the general principles which the Discipline Committee have so far evolved are as follows: (1) Where, as is almost always the case, it is possible to have a brass plate reasonably visible at all hours at the entrance to premises, it is not also necessary to have a further announcement on a fanlight. (2) Where, as is sometimes the case, a projecting sign must be permitted, it is not necessary also to have announcements on the windows. (3) If there is an announcement on the windows, a projecting sign should not be allowed. (4) Windows should not be used to call attention to the extent of a dentist's premises. The Chairman suggested that dentists who received patients in the evenings might use a uniformly coloured plain lamp, either red, or, in districts where some doctors use red lamps, of some other colour, if they desired to distinguish their premises from those of doctors.

Dealing with the Board's scheme for assisting suitable students to qualify, Mr Acland recorded gratification that the scheme now seemed to be established, and was becoming better known amongst schoolmasters and parents. The applications for grants which were considered this autumn were in excess of the help available, with the result that it was possible to make a selection of the most suitable candidates. "There are some," said the Chairman, "who think that the Board is unwise, and is even acting harshly towards those who have to pay for the retention of their names on the Register, by taking steps just now when times are none too easy to add to the number of qualified practitioners. It must be remembered, however, that it will generally be four years before the students who are helped by the Board will qualify, and, further, I am informed that the number of students who are registering this year is certainly not more than those who registered last year, and may even be less. We shall probably be able to assist some 40 or 50 students a year, and if the quality of those assisted is high I believe that much useful work from the national point of view will be done in assisting them."

Dental health propaganda work has made good progress. Organisations of all kinds have shown appreciation of the Board's work. Bodies interested in children, such as the National Union of Teachers and the child welfare organisations; in nursing, such as the College of Nursing and Queen Victoria's Jubilee Institute of Nurses; in industrial workers, such as the Industrial Welfare Society and Industrial Health Education Council; and in general health, such as the National Association of Insurance Committees, have all been willing to coöperate, and it cannot be doubted that much good has already resulted. It is hoped, continued the Chairman, that Women's Institutes also, through the interest of their National Federation, will soon give their aid, for they are often the best means of approach to those who count most in our villages. The Girl Guide movement is also helping, and the Chairman welcomed particularly the coöperation of the rural community councils. By the help of these and other organisations, and in other ways, the Dental Board has already accomplished more than it ventured to hope for a year ago.

A LILLIPUTIAN GARDEN.

THE list of organisms growing in the National Collection of Type Cultures.[1] of which an account appears on p. 1086, is even more fascinating than a catalogue of garden flowers. Their sources are far afield. There are strains of *Aspergillus fumigatus* isolated from penguins, pigeons, black swans, golden eagles, water hens, flamingoes, and owls; there is one of Metchnikoff's original strains of *Lactobacillus bulgaricus;* there are strains of acid-fast bacilli isolated from guinea-pigs inoculated with butter samples in 1912; there are organisms obtained from a wilted pæony, from a tuberculous terrapin, and from the spleen of a skunk which lived, and presumably died, at a skunk farm in the North of England.

It may be observed that those who take up gardening are first intent upon a show of flowers, but afterwards think nothing of such simple pleasures, but are for ever collecting, classifying, dividing, transplanting, manuring, and improving. Of all gardeners the most skilful is the bacteriologist. To him it is given to revel to the full in " the purest of human pleasures "; but whereas Bacon considered this impossible in an area of less than 30 acres, to-day it can be done (out of the wet) in 30 feet. In a small space collection, classification, division, and tender culture of all known microscopic plants is being pursued with zeal and with profit by men and women who are fortunate indeed in their choice of occupation. And the extent of their efforts may be measured by the fact that at the Lister Institute there are well over two thousand living strains, both good and bad, gathered together under one roof.

HOSPITAL ENDOWMENT BY INSURANCE.

Mr. James E. Kavanagh, a prominent official of a New York insurance company, has recently suggested a new application for the principles of insurance—namely, the endowment of universities, colleges, and hospitals. In a speech delivered in Kansas City and summarised in the pages of the *Agents' Journal and Official Gazette*, he states that the United States contain nearly 800 universities and colleges suffering from lack of financial support, only half the money for their maintenance being found by the students, the remainder being a charge upon public and private generosity. He recommends that the difficulty be removed, or at any rate lightened, by students insuring their lives on the endowment plan in favour of the institutions to which they belong. Alternatively, he suggests that they should be canvassed with a view to initiating some organised scheme under which they take out policies in favour of those institutions, the students paying the yearly premiums. Mr. Kavanagh quotes the example of a Roman Catholic educational institution which in 1900 "took out 100,000 dollars of 20-year endowment assurance on the lives of 20 students (that is, 5000 dollars each)," and by 1920 " had drawn 90,000 dollars matured endowments, 10,000 dollars in two death claims, and 5000 dollars bonus."

The idea that our hospitals, established by ancient benefactors, should now be re-endowed by the organised insurance of their medical students will no doubt be noted by those who, in strenuous competition, direct the financial fortunes of these establishments. No doubt, also, the ingenuity of the insurance companies will be equal to the task of working out details, for, as our contemporary observes, the 100,000 insurance agents in this country will not only be furthering a noble work on behalf of our hospitals and other benevolent institutions, but will also be promoting the interests of themselves and their respective offices. They must not expect too much from hospital patients, medical students, or young practitioners engaged in the first struggle to establish themselves; moreover, their chief interest is likely to lie in the educational rather than the charitable side of their medical school. These have the wish to help, but seldom the wherewithal. The idea may fructify amongst the charitably-minded members of the public to whose benevolence so many appeals are already addressed, or amongst members of the medical profession who have happily passed their first struggles and have attained prosperity. Observers of educational conditions in America have noted the remarkable sums which the alumni of a trans-Atlantic school, college, or university will contribute to the support of their *Alma Mater*. In this country it may be that the existence of ancient endowments has made the formation of a similar tradition a less obvious course. But the ancient endowments are sadly inadequate to-day.

ANTITYPHOID AND ANTICHOLERA INOCULATION IN EUROPE.

Dr. Louis Poncet, the champion in France of the medical use of Esperanto, has shown the potentialities of the " auxiliary language " in a very interesting way by his monograph on the practice of prophylactic vaccination against the typhoid group of diseases and cholera in 28 European countries.[1] The statistics were extremely difficult to obtain, and even more so to compile, including, as they do, figures attained by an exasperating diversity of methods and results calculated on widely different scales, and texts of legal enactments where the meaning was often obscure even after close study. The figures are almost certainly less than they ought to be, even in countries where notification is strictly in force, and several are missing, but nevertheless the work gives a valuable comparison both of the application and the results of these prophylactic measures in the principal countries of Europe. The countries are classed under three heads: (1) those where these inoculations have never been compulsory; (2) where they have been widely used, although not legally enforced; and (3) where they are enjoined by law. The second category contains our own country and Ireland only, while the first has some rather surprising names. Everyone knows that there is no hygienic legislation in Albania, and no one expects any great sanitary enterprise from Portugal, but it is striking that neither Switzerland nor Denmark, two of the most civilised States in the world, considers these precautions necessary. Carriers are very severely dealt with in Denmark, and in Switzerland the inhabitants coöperate with the doctors by accepting wholesale vaccination during epidemics. Norway owes its comparative immunity to the care it has taken over its water-supplies.

In Great Britain antityphoid and anticholera inoculation has always been voluntary, even in the Army and Navy, but in practice it became almost universal in both services from 1915 onwards. Even as early as 1909 most of the troops who served abroad were protected. Among our civil population, except for those employed in medicine, nursing, and sanitation, hardly anyone ever applies for vaccination, but our typhoid incidence has fallen nevertheless from 8200 in 1912 to 3800 in 1921. The Anti-Vaccination League comes in for some sharp criticism from Dr.

[1] Vaccination Obligatoire ou Vaccination Facultative contre les Maladies Typhoïdes et contre le Choléra en 28 pays d'Europe. Essai d'enquête internationale par l'Esperanto. Lyon: Office Espérantiste, Rue Gerrandière, 30.

Poncet for its work in hindering the spread of these beneficial measures. In Ireland, where the hostility to vaccination is even greater, the typhoid mortality was 21 per 10,000 in 1923.

Of the countries that come under the third heading, Germany is probably the most important. Vaccination against typhoid has long been compulsory in the Army, but is still optional for civilians, though carriers are pursued vigorously and even to the point of compulsory operation. In other countries, especially in Eastern Europe, where typhoid is a serious scourge, inoculation is compulsory in times of epidemic, and permanently in the armies. The author devotes a long chapter to the progress of these measures in France, where they have always been optional for the civil population; energetic propaganda during the war induced a considerable number of civilians to undergo inoculation. He has published in full numberless orders, circulars, advertisements, and statutes from all sources, and has given every chart and table of figures it was possible to obtain.

Apart from the significance to public health of this laborious collection of statistics, they have probably real value in showing the practical use of Esperanto as a medium of intercourse in international medicine. Dr. Poncet is obviously much more interested in Esperanto than in antityphoid inoculation, and has written a lengthy chapter in its praise; but even he could hardly exaggerate the benefits that the general adoption of some universal language by medical societies throughout the world would confer on medical science.

REDUCED PRICE OF BLUE BOOKS.

SOME months ago we announced [1] an offer by the Ministry of Health to supply public authorities and medical officers with copies of the Registrar-General's statistical reviews at a reduced price. The offer was conditional on the subscription being taken up for five years and on a sufficient response. We understand that although the response has not reached the expectations which had been formed, the degree of success realised has been such as to obtain Treasury consent to the confirmation of the arrangement. Subscribers will accordingly be furnished with copies of "Tables, Part I.—Medical" and "Text" volumes of the Statistical Review for 1924 and future years within the subscription term at the reduced price of 12*s.* 6*d.* per annum. The subscription list cannot be kept open indefinitely, and the higher price will be charged to all purchasers who do not enrol themselves as subscribers before the subscription list is closed. Early application is therefore advisable on the part of those who, not having already subscribed, desire to obtain the benefit of the reduced price.

TONSILLECTOMY FOR RHEUMATIC AFFECTIONS.

THE doctrine of focal infection, as applied to the rheumatic affections, appears sometimes to have been put into practice with more fervour than discrimination, and the number of healthy teeth sacrificed on the altar of this new faith must be very large. But there is much to be said in favour of it, notably in the case of the tonsils, and a paper by Dr. Reidar Gording in *Norsk Magazin for Laegevidenskaben* for September illustrates what can be expected of tonsillectomy, when the indications for it are kept within narrow and well-defined limits. Dr. Gording's material consisted of 260 rheumatic patients, most of whom were treated at the Sandefjord hydropathic establishment. They suffered from one or other of the following forms of rheumatic disease: (1) primary, chronic polyarthritis with an insidious onset; (2) chronic rheumatism limited completely, or almost completely, to the muscular and nervous systems; (3) chronic polyarthritis secondary to acute rheumatic fever; (4) acute articular rheumatism with serous effusions which, as a rule, developed in several joints and was often associated with endocarditis. The patients in these four groups were further classified, according as there were or were not signs or a history of disease of the tonsils. There were 93 patients who belonged to the tonsillar group, and whose average age was 27 years, and there were 167 who belonged to the non-tonsillar group and whose average age was 44 years. Tonsillectomy was not attempted in this group, and it was practised with discrimination in the tonsillar group, only 40 to 50 of the patients in this group being operated on. Only in 34 of these cases was the observation period after the operation long enough to warrant drawing conclusions as to its effects. In 25 of these 34 cases the rheumatic disease had developed more or less directly after an attack of tonsillitis or peritonsillitis. In eight other cases there was a history of recurrent attacks of sore throat and abscesses associated with an exacerbation of the rheumatic condition. Only in one case was tonsillectomy performed solely on the indications afforded by an examination of the tonsils. In two cases the rheumatic disease had lasted only four months, and in four it had lasted about 15 years. The average duration of the disease was about four years. In 22 of the 34 cases the patients stated that the tonsillectomy definitely represented a turning point in their illness; in the remaining 12 cases no benefit could be claimed. In the course of a long discussion of the literature of the doctrine of focal infection, Dr. Gording points out that two courses may be followed: the surgeon may make a clean sweep of the tonsils of every patient with signs of rheumatic disease and then count up his gains; or he may follow the course pursued by Dr. Gording and perform tonsillectomy only in those cases in which a more or less definite relationship between the tonsils and the rheumatic affections can be established. At first sight the latter course might seem the most reasonable and plausible. But is it? With careful classification of all the cases before operation the wholesale procedure might well yield more valuable data than the pick-and-choose method, and that without depriving the individual patient of the chance of rapid improvement following a not very serious operation.

LIPIODOL FOR CEREBRAL LOCALISATION.

THE use of lipiodol injections for the localisation of tumours of the spinal cord is now firmly established. Prof. Sicard, who devised this procedure, has now turned his attention to the possibility of getting this opaque iodine-containing oil into the ventricles of the brain, and Rimbaud, Lamarque, and Janbon [1] have recently reported a successful application of Sicard's method to a case of general paralysis in which they obtained X ray pictures of all the ventricles. It is obvious that direct intraventricular injection of lipiodol presents too much difficulty and risk to be a feasible proposition, and Sicard's method has been to use an emulsion of cerebro-spinal fluid and lipiodol of a low density which rises to the highest point of the nervous system bathed by this fluid. The technique adopted was to perform lumbar puncture in the ordinary way with the patient sitting, and allow about 10 c.cm. of cerebro-spinal fluid to escape. A glass syringe is then fitted to the lumbar puncture needle and a further 5 c.cm. of fluid withdrawn. The syringe is detached and a stylet placed in the needle to prevent escape of the fluid, while 5 c.cm. of low density lipiodol are drawn into the syringe and well shaken until an emulsion is produced. This is then slowly injected through the lumbar puncture needle into the spinal canal. Sicard's original technique was very similar, except that his emulsion was made in a separate vessel by stirring with a glass rod. An X ray picture of the skull taken one hour after injection, during which time the patient remained sitting, failed to show any abnormal opacity, but in a second picture taken three days later definite shadows could be seen in the regions of the lateral and third ventricles. The patient showed no ill-effects whatsoever, even when leaving the hospital and taking a tram journey after the first radiograph. Encouraged by their results the authors made a second injection of lipiodol eight days later and obtained very striking radiographs at the end of 48 hours. These showed the outline of the lateral, third, and fourth ventricles, and also extraventricular shadows corresponding to the fissure of Sylvius and the insula. Such an addition to the radioscopy of the brain opens up great possibilities in the localisation of tumours and might also possibly assist in determining whether the intraventricular injection of serum is necessary in cases of cerebro-spinal fever where basal adhesions prevent the upward passage of serum injected by the lumbar route. It is also suggested that the close contact of iodine with the brain may have a possible therapeutic application in cases of cerebral syphilis.

UNIFORM NOMENCLATURE OF DISEASES.

A "Nomenclature of Diseases" was first issued in 1869 by the Royal College of Physicians of London, the aim of the compilers being, as stated in the preface, "to prepare a nomenclature suitable to England and to all countries where the English language is in common use." Half a century later American medicine found a similar need and the first report of the Committee on Mortality Statistics was submitted at the Cincinnati meeting of the American Public Health Association in October, 1916, and appeared in *Public Health Reports* (Sept. 22nd, 1916. Reprint No. 363). A second report was presented to the Washington meeting in 1917 (P.H. Reports, Sept. 28th, 1917. Reprint No. 440). A third report of the Committee, over which Dr. Haven Emerson presides, is before us now.[1] The natural desire of every public health administrator to see an accurate system of death certification uniform throughout the United States meets with the unsolved difficulty of the federal aims for uniformity infringing the supposed rights of the several States. When this has been adjusted the next step should be an easy one, when the Royal College of Physicians undertakes its decennial revision, due in 1928. It should then be possible, in agreement with the United States of America, to prepare a revised "Nomenclature" suitable for all the English-speaking peoples. Such a revision would concern the sectional headings as used in the table of contents to the "Nomenclature" (fifth edition, 1918), as well as the titles adopted to distinguish the several diseases. From a survey of the conclusions reached by the American Public Health Association, there should be no difficulty in bringing about agreement on one principal title. The American report includes an approval of a large number of synonyms, some of which have been discarded by the Royal College of Physicians after careful consideration. Most of the remainder of the approved synonyms may be regarded as subordinate to the principal titles and not as substitutes. The American Committee have to keep in mind the practice of the Bureau of the Census and of the various State and Municipal Registration Offices. It is the "International List of Causes of Death" which should form the basis for agreement with the next revision of the "Nomenclature" of diseases by the Royal College of Physicians.

PARATYPHOID IN SWITZERLAND.

Dr. W. Silberschmidt,[2] of the Institute of Hygiene of Zurich University, remarks that though a knowledge of paratyphoid bacilli dates back to nearly 30 years ago, when they were first described by Achard and Bensaude in France and subsequently by Schottmüller in Germany, who was the first to distinguish paratyphoid A and B bacilli, not much has been published on the subject of paratyphoid fevers in Switzerland. During the period 1920–24 340 cases of paratyphoid were notified to the Swiss federal authorities, 45 being reported in 1920, 56 in 1921, 79 in 1922, 115 in 1923, and 45 in 1924. Like other infectious diseases of the alimentary canal, most of the cases were observed in the summer and the smallest number in the first three months of the year. The value of these statistics, however, is not very great, as they are far from complete, notification of paratyphoid not being compulsory throughout Switzerland and the diagnosis often not being made in the absence of bacteriological examination. During the period 1920–24 cases of paratyphoid were observed in almost all the Swiss cantons. The most striking feature was that they were almost always isolated cases. The towns of Bâle and Zurich, however, were exceptions, as they headed the list with 53 and 31 cases respectively during the period mentioned, with a maximum of 36 and 18 in 1923. This does not mean that these two towns were more affected than the rest of Switzerland, but the larger number of notifications merely indicates that notification of contagious diseases was carried out more conscientiously and greater use was made of bacteriological examination at Bâle and Zurich than elsewhere. In the canton of Zurich bacteriological examination of the stools, urine, and blood is carried out gratuitously in all cases suspected to have typhoid, paratyphoid, or infectious enteritis, more than 800 examinations of the kind being made annually at the Institute of Hygiene. About 20 years ago an epidemic of paratyphoid caused by consumption of salt-water fish occurred at Zurich. Formerly many cases were due to consumption of meat from diseased animals, but at present, owing to stricter supervision of the slaughter-houses, the number of these cases has diminished. As in typhoid fever, contamination may take place by contact, but according to the Swiss statistics this mode of propagation is not very frequent in paratyphoid.

THE second Victor Horsley memorial lecture will be delivered by Mr. Wilfred Trotter in the house of the British Medical Association on Friday, July 9th, 1926.

Rebuilding of Middlesex Hospital.—In order that the rebuilding may begin, the west wing of Middlesex Hospital will be closed in January. The governors have acquired an old Metropolitan Asylums Board infirmary in Cleveland-street, a few hundred yards away, to which the wards in the wing will be removed. This "Cleveland-street Annexe" has had to be given a new roof and new floors, to be drained and replastered, and it has now to be completely equipped as a hospital with two operating theatres and all the necessary apparatus. It will accommodate 200 patients, and as soon as they are removed the reconstruction of the old hospital will begin. About £212,000 has now been received towards the £500,000 that the work will cost.

Fellowship of Medicine and Post-Graduate Medical Association.—Mr. G. R. Girdlestone will lecture on Tuberculosis of the Spine on Monday, Nov. 23rd, at 5.30 P.M., in the Lecture Hall of the Medical Society of London, 11, Chandos-street. All members of the medical profession are welcome. The following courses begin on Nov. 23rd: Medicine, surgery and gynæcology at the Royal Waterloo Hospital; nervous diseases in the out-patient department of the West End Hospital, 73, Welbeck-street, and a late afternoon course (4.30 to 6 o'clock) for the convenience of the general practitioner at the London Temperance Hospital. On Nov. 30th to Dec. 13th the Infants Hospital will hold a special course occupying the afternoons only. The Hampstead General Hospital has also arranged a late afternoon course for the convenience of the general practitioner from Dec. 7th to 19th, covering all branches of medicine, surgery, and the special departments. There will be a course in dermatology at the Blackfriars Hospital for Diseases of the Skin from Dec. 7th to 19th. Instruction will be given in the out-patient department, and venereal clinics will be held twice weekly. A copy of each syllabus and the Fellowship general course programme will be forwarded on application to the secretary, 1, Wimpole-street, London, W. 1.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CXLVIII.—CHRONIC NASAL DISCHARGE IN INFANTS.*

Coryza Neonatorum.

ACUTE rhinitis in infants is of importance, because this affection may produce intranasal changes with a chronic discharge. Moreover, when older children are brought to us with "chronic catarrh," which is said to have begun with "a cold in the head" at or shortly after birth, a knowledge of the varieties of coryza neonatorum assists in elucidating the pathogenesis and in suggesting suitable treatment in each case.

There are three varieties of the acute rhinitis from which an infant may suffer shortly after birth:—

1. Coryza neonatorum simplex, which is due to air-borne infection and which resembles the cold in the head of adults.

2. Coryza neonatorum blennorrhoica, in which the discharge is profuse and purulent from the onset and is caused by leucorrhœal or gonorrhœal discharge in the mother's vagina at the time of birth; the nose is infected directly or from the eye through the naso-lacrymal duct.

3. Coryza neonatorum syphilitica, the nasal symptoms of which are manifestations of the secondary stage of inherited syphilis.

At an early period of the illness it may be difficult to determine which of these affections is present. It is usually found, however, that when a healthy infant contracts coryza after birth the symptoms appear later, are less severe, and of shorter duration. In the blennorrhœal variety the onset within the first day or two of life of an abundant and persistent discharge of pus, sometimes containing gonococci, and the swelling of the nose and crusting of the nostrils are outstanding features. Snuffles may be the first and for several weeks the only sign of a syphilitic infection. Confirmatory evidence of the existence of this diathesis is supplied by the characteristic signs on the buttocks, around the anus, and at the angles of the mouth. This specific coryza differs from the other varieties also in that the nose is drier and the nasal discharge is thicker and tends more to crust.

Coryza neonatorum, whatever its origin, is always a serious ailment owing to the swelling of the lining membrane of the nose and accumulation of secretion which prevent nasal respiration. The instinct to breathe by the nose is strong and mouth-breathing is not readily adopted, so that a constant tendency to suffocation is produced. The nasal obstruction interferes also with sucking, which has to be stopped at very brief intervals to allow of breath being taken. The efforts to obtain a sufficient supply of air and food cause rapid exhaustion, and when to this are added complications in the larynx and chest owing to an extension of the inflammatory process and the low vitality of the majority of these little patients, the outlook becomes extremely grave.

The indications in coryza neonatorum are: to maintain the strength, diminish the catarrh, improve the nasal patency, guard against infection of the conjunctiva if it has escaped, and treat any underlying dyscrasia. It is necessary to act promptly. Spoon-feeding or a tube must be used. If the inspiratory efforts tend to cause aspiration of the tongue the infant must not be laid on its back. The crusts filling the nostrils should be softened with warm almond oil or paroleine and removed. The pus and mucus in the nasal fossæ should be liquefied by instilling at intervals with a medicine dropper a few minims of a warm solution of bicarbonate of soda (3 gr. to 1 oz.) or other alkaline detergent. Great care must be taken that the fluid does not reach the naso-pharynx in any appreciable amount owing to the danger of causing otitis. When the discharge is thinned it should be mopped or sucked out of the nose by means of an all-rubber pear-shaped syringe having a long tapering end. The catarrh is best treated by silver preparations. The nitrate is most in favour instilled or used as a paint (2 per cent.) and less often as an insufflation (2 parts with talc 100 parts). Argyrol (10 per cent.), protargol (4 per cent.), collosol argentum, &c., are also recommended. If obstruction is great owing to swelling of the mucous membrane the passages may be painted every two hours with adrenalin solution (1 in 10,000). Cocaine is not admissible except in weak solutions (½ per cent.) and at long intervals, and menthol has produced fatal glottic spasm in babies. The skin of the nostrils and upper lip should be smeared with cold cream in order to counteract the tendency to excoriations and eczema.

In congenital syphilis constitutional treatment is of first importance; the local measures outlined above, or, if considered preferable, a paint of colloidal mercury or insufflations of calomel and sugar (1 in 25) may be employed. When there is tendency to dryness of the nose tampons soaked with diluted Mandl's solution (iodine gr. 3, iodide of potassium gr. 12, glycerine 1 oz.) may be introduced.

Osteomyelitis of the Superior Maxilla.

Osteomyelitis of the superior maxilla causes a variety of nasal suppuration occasionally met with. This affection in most cases sets in suddenly one to three weeks after birth, with general disturbance and unilateral local signs. Of the latter, the principal are swelling of the eyelids, cheek, alveolus, and palate on the affected side; formation of an abscess below the inner angle of the eye; and discharge of pus from the eye, nostril, and alveolus. Later, a tooth protrudes through the swollen alveolus and being loose is easily removed. Access is thus obtained to a comparatively large cavity containing pus and often communicating with the nose. This cavity is a dental sac, but it has been repeatedly mistaken for the antrum—which in early life is smaller than the sac—and the affection has been described as empyema of the antrum of Highmore in infants. Areas of bare bone may be detected in the alveolus and outer wall and floor of the nose; and during the later course of the disease sequestra are extruded. In some cases that have succumbed the whole upper jaw has been found necrosed. Metastases occasionally take place. The disease has been attributed to various causes, but the most probable is a blood-borne infection.

In the early stages of the disease special attention should be paid to nutrition of the infant in order to help it to withstand the effects of a long and debilitating illness. Free escape should be provided for purulent collections, but it is rarely necessary to incise the skin below the eye, and if possible this should be avoided. A tooth projecting through the gum should be removed. The patient may come under our care when there is merely a purulent discharge from the nose, alveolus or a sinus. Search should then be made for sequestra and their removal effected provided this does not entail a severe operation, which is badly borne and liable to be followed by disfigurement.

A. BROWN KELLY, M.D., D.Sc.Glasg.,
Consulting Surgeon for Diseases of Throat and Nose, Victoria Infirmary, Glasgow.

NUNEATON: CALDECOTE HALL. — The Central Council of the Church of England Temperance Society announces that on Tuesday, Dec. 8th, at 1 P.M., Sir William Joynson-Hicks, Bt., will open Caldecote Hall as a home for cases of certain types of functional nervous disorders.

---

* An article by Mr. Brown Kelly on Chronic Nasal Discharge and Sinusitis in Children will appear in THE LANCET next week.

Special Articles.

ROYAL COMMISSION ON LUNACY AND MENTAL DISORDER.

The Commission resumed its sittings, after the summer interval, on Nov. 10th, Mr. Hugh Macmillan, the Chairman, presiding.

Evidence of Sir Maurice Craig.

The first witness was Sir Maurice Craig, lecturer in psychological medicine at Guy's Hospital and hon. consulting neurologist to the Ministry of Pensions. He said he was for 15 years assistant physician to Bethlem Royal Hospital, and for a year was an assistant medical officer at the West Riding Mental Hospital, Wakefield.

Certification or Notification.—Sir Maurice Craig declared that the Lunacy Acts of 1890–91 were intended to protect the liberty of the subject, but in effect they had interfered with the liberty of persons intending to use them. Medical treatment took only a secondary instead of a primary place. No branch of medicine had been so trammelled by legal enactments as had psychological medicine, hence its progress had been slow, and many medical practitioners were shy of taking it up. In connexion with the certification of people of unsound mind the legislature had placed an obligation on the medical man which had nothing to do with medicine. Certification, indeed, he regarded as an embarrassment to medical science, as it confused the relationship of the physician to the patient, and his own view was that it was responsible for much recoverable mental disorder being permitted to become chronic before suitable treatment had been entered upon. Often mental disease was of slow development, the patient was conscious of his gradual mental failing, and dreaded that he might become insane. He needed to be reassured and have appropriate treatment early. Some medical men were afraid of undertaking treatment of these cases, the conditions attending certification acting as a deterrent. Yet it was practically unknown for a person to take action against a medical man for malpraxis when certification had not been reached. He said it was not surprising that medical men were refusing, in increasing numbers, to sign certificates of lunacy, the reason given being that they did not know what insanity, in the legal acceptation, meant. Sir Maurice Craig said the harm done by certifying patients in the early stage of their illness far outweighed any advantages. He would like to see certification abolished, at least temporarily; this would do much to bring mental disease into line with physical disease. Mental patients could be placed in three categories: (1) the willing and coöperative, (2) the passive and indifferent, (3) unwilling and hostile patients who demanded their freedom. One of the results of the temporary abandonment of certification would be, the witness considered, a large proportional increase in cases in the first category, as patients would soon find that application for treatment of their mental condition was not likely to endanger their personal liberty. Cases in this first class should certainly be treated in special hospitals or clinics, buildings which were not even in the same grounds or precincts as properly named mental hospitals. A non-volitional patient should be granted the same freedom from certification as a willing one, at least for such a period as would make possible his recovery. Patients in the third category should continue to be treated in the same kind of institution as the present mental hospital, but under some form of provisional notification or provisional certification at first. He agreed with borough or county hospitals being permitted to take voluntary patients, and added that until such time as fresh accommodation could be found the non-volitional group of cases should be admissible to those institutions without having to be certified. He favoured the perpetuation of licensed houses, and thought the willing cases should be able to go to them for treatment on their own written request without it being necessary for them to apply to the central authority for permission. Sir Maurice Craig thought it was desirable to permit, by legislation, non-volitional cases to be treated on notification only—i.e., short of certification—while the unwilling group could be under some form of provisional certification. Where patients were given the choice they usually preferred private single care; he would himself.

Mental Symptoms Associated with Bodily Illness.—He stressed the necessity of recognising the acute mental conditions which were associated with bodily illness, such as pneumonia. He would have a routine inspection of all nursing homes, ordinary and special, and would like this largely to take the place of so much inspection of the patient. At one time he did not favour this supervision being carried out by the Board of Control, as he then considered that body was too much steeped in the traditional treatment of mental disorder; but he now appreciated how much the Board had taken up modern views on the subject, and thought it was quite fitted to undertake this supervision, including cases in the early stage of mental illness. Still, he thought the medical side of that Board should be strengthened, as contrasted with the legal constituent. At Guy's Hospital there was one neurological department, and in that were included cases of early mental disorder. This did away with a reluctance on the part of patients to attend an obtrusively mental clinic. The activity of this department was steadily increasing.

In answer to a question by Sir Humphry Rolleston, the witness said he felt himself in a difficulty when he had a case of mental disease as a sequel to pneumonia, because though from the hospital standpoint the patient was regarded as primarily suffering from pneumonia and the mental trouble was secondary, that was not so in the eyes of the law. Yet it would be a very serious step to certify such patients, especially in view of the detrimental effect of the certification on their subsequent life. Asked whether he advocated a measure to afford further protection to the medical man dealing with cases of insanity, Sir Maurice Craig said he personally would not seek such a measure, because if he were charged with a wrong procedure in such a case it would merely mean he was being charged with behaving like a human being. He thought increased research would show that more and more mental states had a definite causal relationship with physical disorders. He had always encouraged the idea that mental ailments were a branch of general medicine. At the Cassel Hospital, at Penshurst, Kent, there was always a waiting-list of 40 to 50 non-certified cases. These cases, on admission, paid 5 guineas per week, an inclusive fee, and there were two wards at 3 guineas. The cases were followed up, and a return made to show what had happened to them.

Following a discussion on the mental condition of a man who was insane only at certain periods, the Chairman said he felt that the doctor should not be subject to be influenced by the idea that he might get into trouble for what he did; he should be able to approach a case without fear or favour, and he should be protected, always assuming that he acted in good faith. In the course of answers to further questions, the witness said that to neglect to make provision for the early treatment of mental disorder was equivalent to telling a patient who came feeling ill that the illness could not be treated until there were cavities in the lung and hæmoptysis occurred, but after that he would be treated and looked after for the rest of his life. He also had a great objection to early mental cases being placed with confirmed cases, which constituted for them a tragic outlook. He favoured the general hospital being a clearing-house, where new cases could be investigated and passed on.

Sir Humphry Rolleston suggested that if notification were substituted for certification it might only be a matter of time before the former was viewed, in the popular mind, in the same way as certification now was.

Mr. Jowitt put to Sir Maurice Craig the disadvantage to fresh patients of being placed in noisy surroundings, and the reply was that the witness was very much in favour of more single rooms ; he had often wondered how patients were expected to sleep in a dormitory. He believed such noise and lack of sleep might drive a patient over the borderline.

Sir Humphry Rolleston reverted to the question of the reluctance of the profession to certify, and asked the witness whether he thought it well that there should be a specialised class of medical officer to deal with this subject, allocated to districts, as in the case of tuberculosis and venereal disease officers. Sir Maurice Craig replied in the affirmative, adding that such officer should not himself be in practice. In further replies he said he did not think any private mental home would object to revealing its balance-sheet to the Board of Control ; he did not see any need to make such statement public.

The Student's Curriculum.—Questioned as to the inclusion of the study of insanity in the curriculum, witness said the desire was to get this subject recognised along the same lines as clinical medicine, though he well knew how burdened the curriculum was already. It was essential, he thought, that every medical student, on entering practice, should know something about the mind and its working, and he would accord more prominence to that, even if it were necessary to curtail something else. At Guy's Hospital Medical School courses on mental neuroses would be given, and it was hoped to proceed to a systematic study of the mind. Personally, he would have both an extended scope and some knowledge of psychiatry possessed by every qualified student.

Evidence of Dr. F. L. Golla.

Dr. Frederick Lucien Golla, pathological director of the Laboratory of the London County Council, was the next witness. He considered it desirable that facilities should be afforded for pathological research, not only in individual mental institutions, but also at central institutions, throughout the country, the latter offering assistance and advice to the smaller laboratories, and undertaking training of asylum medical staffs.

Research Facilities at the Maudsley Hospital.—That was the scheme under which London worked. He himself did his work at the Maudsley Hospital, where he had in coöperation three skilled assistants, engaged whole time. Four assistant medical officers from mental hospitals acted for a period of three months at the laboratory as a training, and the choice was determined by the medical superintendents or the assistant officer's own application. This procession of four assistants went on throughout the year. All the Wassermann and other tests for the London County institutions were done at his central laboratory. Dr. Golla said he also engaged in research initiated by himself, and supervised that done at the other asylum laboratories in the County, and suggested subjects for study at those laboratories. There was, at the Maudsley Hospital, a department for physiological psychology, for investigating the physiological concomitants of mental disturbance ; they investigated the changes in metabolism occurring in association with various mental states, the reactions in those states, and, in another department, questions of more or less pure psychology were dealt with, and a record was kept of the family histories of all the cases and their coördinate relationships. All that work he regarded as of the greatest importance. He thought the ordinary medical officer should be encouraged to investigate cases; it would assist diagnosis and in the suggestion of remedies. An enormous field was opened by this work ; we were definitely behind several other countries in this matter. He said that in psychology there was no such clearly cut classification of disease as in physical medicine, hence there must be means of investigating the patient himself, and the London County Council had recently effected great progress in providing these facilities. In the provinces four or five counties could be grouped for coördination with one central institution. Outside London, with the exception of Birmingham, Cardiff, and one or two other centres, there was not much research being done in mental disease. He thought medical officers should be granted adequate leave from their duties so that they might continue their studies, and time spent in research should be regarded as part of the duties of the asylum medical officer. He favoured the idea of local authorities making grants-in-aid to such institutions in the provinces. The malarial treatment of general paralysis of the insane was a good instance of a definite advance due to a modern discovery ; again, true asylum dysentery, at one time very prevalent, was now practically unknown, an enormous economy in the matter of money and life.

Evidence from the Central Association for Mental Welfare.

Dr. A. F. Tredgold, Miss Evelyn Fox, and Miss F. Andrew attended to give evidence on behalf of this body, mainly concerning adolescent mental disorder, which was, they affirmed, widely prevalent and was a menace to the general state of society. These cases were not incipient, and no existing administrative provision covered them, yet they needed supervision, training, and treatment of a kind not possible in the home. The establishment of training homes for these cases was urged, where skilled treatment would be available. It was suggested that admission to such establishments, if set up, should be on the application of a parent or guardian, or in the alternative, of a local authority backed by a medical certificate that the case was a suitable one.

Mr. Jowitt questioned whether this matter was not outside the terms of reference, and following upon this an argument took place as to whether these cases really came within either the Mental Deficiency Acts or the Lunacy Acts. The Chairman thought the category was so indefinite that charity might meet the need.

Sir Humphry Rolleston asked Dr. Tredgold as to the degree of prevalence of mental disorder accompanied by misconduct, and the witness replied that the number of cases of mental disorder which had recently been met with as a sequel to encephalitis, chiefly lethargic, rendered the problem more acute. Sir Humphry Rolleston said he thought it possible a case could be made out for an amended Mental Deficiency Act.

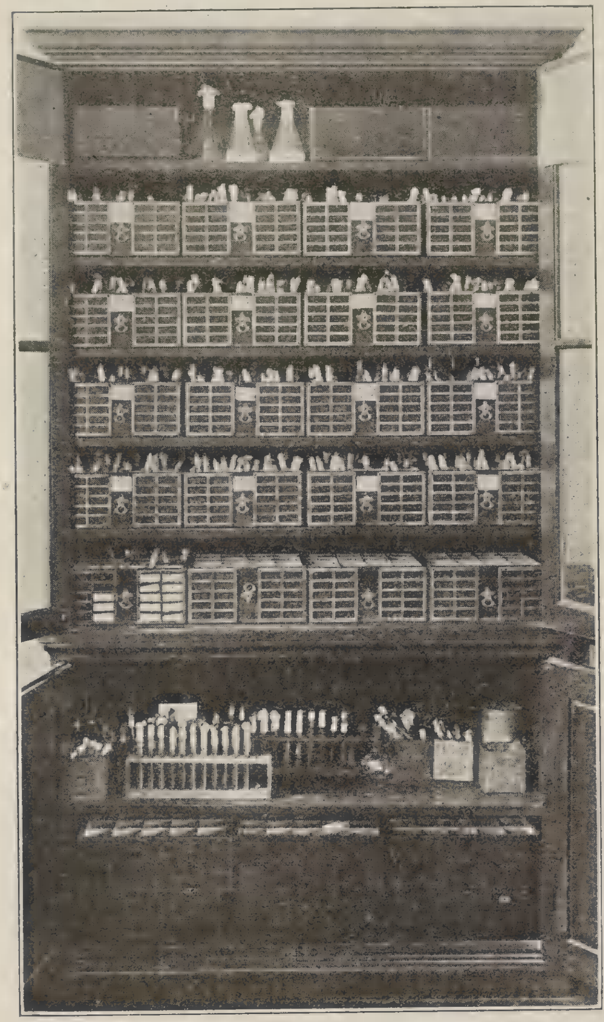
Another submission tendered by the witnesses was that there should be an adequate investigation, from the mental standpoint, of all persons criminally charged in whom there was reason to suspect mental defect.

The Commission then sat privately, and adjourned to a day to be notified.

PHILADELPHIA: ALVARENGA PRIZE.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $300, will be made on July 14th, 1926, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published. The essay should represent an addition to the knowledge and understanding of the subject based either upon original or literary research. Essays must be received on or before May 1st, 1926, by the secretary of the College, 19, South 22d-street, Philadelphia, Pa., U.S.A., from whom all further information may be obtained. The Alvarenga Prize for 1925 was awarded to Dr. Raphael Isaacs, of Boston, Mass., for his essay on the Nature of the Action of Roentgen Rays on Living Tissue.

THE NATIONAL COLLECTION OF TYPE CULTURES.

It was in 1920 that the Medical Research Council made arrangements to maintain at the Lister Institute this admirable collection of type cultures. In the past the demands of biologists and bacteriologists for an available supply of authentic strains of bacteria and protozoa had never been fully met, and the need for such a supply was particularly felt in medical research work, both for the study of principles and methods in bacteriological investigations and for systematic classification of species and strains. The Lister Institute had assisted bacteriologists at home and abroad as far as its private resources permitted and there was a certain amount of international coöperation, but conditions were far from satisfactory. The National Collection has filled the gaps. At first attention was concentrated on obtaining fully authenticated strains of pathogenic organisms, but as opportunity has offered additions have been made of those of economic importance. In 1921 it became apparent that mycologists were in need of a collection on similar lines, and by coöperation this was added at the Lister Institute. Though the mycological section is at present limited to a few hundred strains it is hoped to collect and maintain cultures of all fungi of importance in plant pathology, medicine, veterinary science, technology, and soil biology, besides specially rare or interesting species.



A cabinet in the collection of type cultures at the Lister Institute.

To keep up so large an establishment is a task of some magnitude and gives ample opportunity for research on economical and labour-saving methods of subculture. The work is so apportioned that a certain number of organisms come up for subculture every day and a diary is kept in which the dates are entered up many months in advance. There is, therefore, no fear of any organism or group of organisms being inadvertently overlooked. Some require frequent subculturing, such as gonococci, *M. catarrhalis*, *B. bulgaricus* and *acidophilus*, and anaerobic actinomyces. Others are extremely hardy, for example, *B. anthracis*, most of the anaerobes, *B. coli*, and other coliforms, *B. typhosus*, yeasts and various moulds (penicillium and aspergillus). Many of these could be safely left for a year, but in practice no organism is left more than six months without subculturing. In between these extremes there are many which are subcultured at monthly and two-monthly periods. Some species of pathogenic organisms (e.g., *B. anthracis*, *B. avisepticus*) appear to maintain their virulence for many years in artificial cultivation. Others become rapidly attenuated. At the Institute a few types (streptococci, *B. pestis*, *B. enteritidis* Gaertner, *B. tuberculosis*) are kept virulent for animals and an endeavour is always made to exalt pathogenicity on special request. Cultures of *B. tuberculosis* lose their virulence on long cultivation in the laboratory; freshly isolated strains of the bovine variety, for example, lose their virulence in about three years.

But, apart from research, such a collection requires and deserves to be used as much as possible by practising bacteriologists. The new edition of the catalogue is intended to stimulate microbiologists in this and other countries to avail themselves further of the resources of the collection and also to deposit important strains for maintenance and reference. Every effort is made to meet the needs of applicants for cultures, and help is given in identifying strains submitted for the purpose. Although the Director can only accept cultures for the collection at discretion, it is hoped that this will not deter workers from forwarding strains of even the commonest types of organism. These are useful in maintaining an adequate representation of strains of recent origin, and studies in classification are aided if large series of authentic specimens of closely related species are made available.

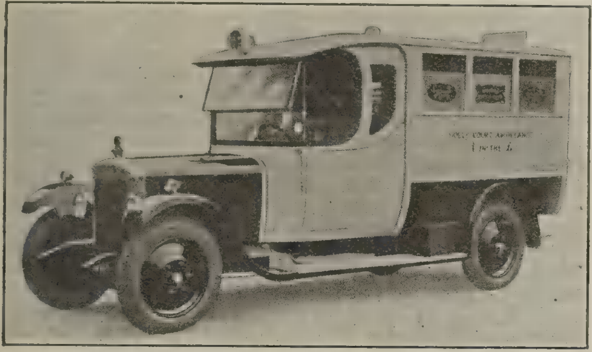
Communications on the subject may be addressed to the Curator, National Collection of Type Cultures, Lister Institute, Chelsea, London, S.W. 1.

AMBULANCES AT OLYMPIA.

Although the cars shown at the Commercial Motor Exhibition, held at the end of last month, were very varied, and included vehicles for almost every purpose, it was disappointing to find only six ambulances. The ambulance is one of the most highly specialised forms of motor vehicle there is; it must be fast and very comfortable, and perfectly fitted, lit and warmed, and must also be designed so that it can be readily cleaned and disinfected. Ambulances, therefore, fall into two classes. The first is designed by motor manufacturers to fit their own commercial chassis, like the Bean, the Berliet, and the Austin; the second is designed by ambulance builders to fit the largest and most luxurious private-car chassis, and of these hardly a representative was to be seen. Their advertisements are familiar to readers of medical journals, but for some reason they did not exhibit. The Pickford ambulance, on a 25/85 Daimler chassis, was the only true example, and the Talbot 25/50 was an instance of a first-class ambulance made by a motor-car firm. These are the cream-white vehicles with the musical gong that are so familiar in the London streets. The car-makers' ambulances are by no means to be despised, as, although they are not as luxurious and fastidiously equipped as the work of ambulance specialists, they are yet extremely efficient, and as motor vehicles are absolutely reliable.

The Bean ambulance is designed to provide essential equipment at the lowest possible price; "extras" of every kind are listed so that the purchaser can choose just what he wants. The chassis is the 20–25 cwt. Commercial, with four speeds, and 5 in. straight-sided pneumatic tyres, and for £500 is fitted with two stretchers and a hinged seat. Heaters, wash basins, starter, headlamps, &c., are extras. The ventilation system is excellent, and the body is easily disinfected. The finish is "self" coloured—i.e., varnished wood panels—and the springing is very good. All possible extras, including four wheel brakes and wash-basin, total £90.

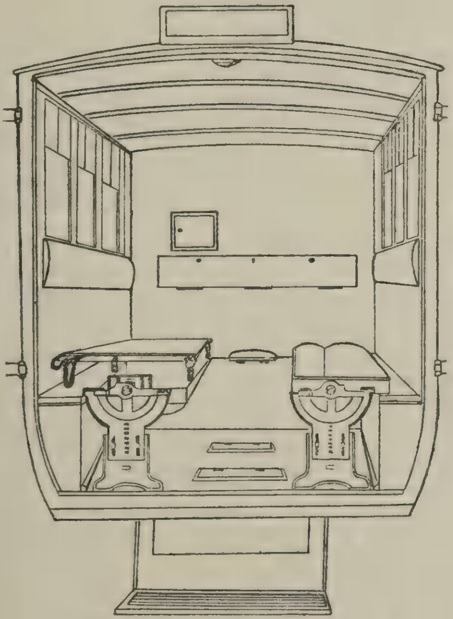
FIG. 1.



The J.H.C. type ambulance, fitted on a 25 h.p. Daimler chassis.

Automobiles Berliet fit ambulance bodies to all of their 15, 20 and 30 cwt. chassis. The model at Olympia was the 20 cwt. 15·9 h.p., slightly larger than the Bean, and also varnished inside and out in self-colour. There is room for two stretchers, of which the bottom one is fitted with 12 in. rubber-tyred wheels, so that a patient can be wheeled any distance. If the ambulance is intended for infectious cases the body is specially prepared with all corners neatly blocked and rounded off, and the stretchers are fitted with Dominion wire mesh, which can easily be disinfected. Four gears are fitted, and the price is £525. The body of this machine is made by Wilson and Stockall, of Bury.

FIG. 2.

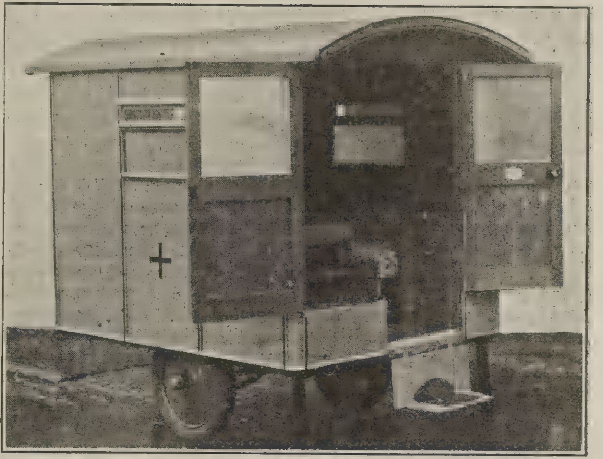


Interior of J.H.C. ambulance.

The Austin ambulance is fitted to the well-known Austin 20 chassis, with a lowered gear ratio. It is a handsome vehicle, finished in dark green, with two large frosted-glass windows on each side. The top stretcher lowers with the reliable and popular parallel-ruler and worm-wheel device. The back doors expose the whole interior when open, and shut with a slam lock; there is a further safety lock to prevent theft. A sliding door can be fitted in front beside the driver if required, to facilitate the entry of sitting cases. The interior is enamelled white, with linoleum or rubber tiling on the floor, and is very fully equipped. The price is £725 at the works.

The Talbot 25/50 hospital ambulance is a splendid vehicle. The stretcher-frames are made of non-staining steel alloy, and run on rubber-tyred wheels; the stretchers can be replaced by upholstered seats with padded back-rests. The car will take two stretcher cases, one stretcher case and four sitting cases, or eight sitting cases. Two folding seats are fitted for attendants. The interior of the roof and walls is smooth-surfaced and has rounded corners, and the lower portion of the sides and floor are sheathed in aluminium. Heating pipes fed from the exhaust run under both seats. Full medical equipment is fitted, and two roof lights, roof ventilation, an electric fan, and an inspection lamp. The price is £850. The Accident type, at £785, is identical with the Hospital model, except that it is less lavishly fitted and has no heater nor fan.

FIG. 3.



Ambulance trailer.
By Eccles Motor Caravans.

The ingenious "penny-in-the-pound" scheme adopted by the Sheffield Joint Hospitals Council has not only maintained the hospitals of Sheffield on an adequate footing, but has made them almost prosperous. A part of the Council's activities is the provision and maintenance of a fleet of ambulances, and they have chosen one of the most luxurious and beautifully equipped machines obtainable. The makers are E. H. Pickford and Co., Ltd., of Sheffield, who designed a type of body known as the J. H. C. (Fig. 1), especially to suit the requirements of the Council. The chassis is the 25/85 h.p. 6-cylinder Daimler, and the cost of the ambulance, complete, is £1130, or £1030 on the 20/70 chassis. Four wheel brakes are fitted. The stretcher equipment (Fig. 2) is beautifully designed. Four stretcher cases can be carried, and the two top racks lower instantaneously with a special extension device which projects them clear of the back of the ambulance so that cases can be easily laid on them and swung into place, and the whole stretcher equipment can be quickly folded up to make room for ten sitting cases. Splints, utensils, and a medicine chest are included in the equipment, the whole of which can be easily taken out to cleanse and disinfect the interior. The finish is left to the customer's choice, but the model shown was in black and white. It is certainly one of the finest ambulances on the road.

Few hospitals or municipalities can afford ambulances as expensive as this, however, and many cottage hospitals and nursing homes find even the cheaper models outside their reach. For these there is a really admirable little vehicle made by Eccles Motor Caravans (Fig. 3), a trailer which, although it is only 7 ft. 3 in. by 5 ft. 6 in. by 5 ft. 9 in., will take two stretcher cases in comfort, and possesses the completest outfit down to hot-water bottles and blankets. It can be trailed at a very fair speed behind any 10 h.p. car, and costs only £135. It has automatic brakes of its own, and is beautifully finished inside and out. The "Eccles" sounds such a godsend to the small hospital that it will be surprising if it does not become extremely popular.

BERLIN.

(From our own Correspondent.)

Closed Pharmacies.

Your Paris correspondent lately complained of the drawbacks of the closure of Paris pharmacies. Things are arranged otherwise in Berlin. Until the war the pharmacies were compelled to be open day and night, Sundays and holidays included. There was always a chemist on night duty in each pharmacy who received the prescriptions through a hole in the shutters, whilst the individual fetching the medicine had to remain outside in the street. During the war, when the great majority of chemists and their assistants had joined the army, the Government, under the powers conferred upon them, ordered that of four pharmacies only one had to be open on Sundays, holidays, and at night. The other pharmacies, even when they wished to keep their shops open, were not entitled to do so. This system was maintained after the war, although there was no longer a shortage of qualified assistants to do night duty. A licensed chemist in Hanover, who tried to keep his shop open day and night, was prevented by the local police under the regulations issued during the war. He therefore brought an action against the police, pleading that the regulations had been contrary to the apothecaries law, and that they had expired with the lapsing of the Emergency Act. The High Court indeed gave a judgment that this was really the case, and that the chemist had the right of having his shop open day and night. The German Association of Licensed Chemists and the Union of Assistants, who had been very much satisfied with the state of things during the war, thereupon decided to maintain it by agreement amongst themselves. The system certainly works very satisfactorily from the point of view of the public. To save the public unnecessary trouble there is on every closed pharmacy a poster indicating the nearest pharmacies open, on a system of weekly rotation. Moreover, every medical man residing in Berlin receives in the beginning of the year from the Chemists' Association a calendar with a complete list of the pharmacies which are open by rotation at night or on Sundays. In this way there is no need for a sick person to do his pharmaceutical shopping early. It never occurs that a pharmacy described as open is actually closed, as stated by your Paris correspondent. It must, however, be considered that the licensed chemists in this country are under strict Government control, and are regularly visited by the district medical officer of health, together with a Government chemist. Contrary to the law in France, there is a "numerus clausus" for licences. A chemist after having duly qualified is not entitled to open a shop at once, but he must wait until a licence becomes vacant by the death of a licensed chemist or until the Government grants a new licence when there is a need for the increase of pharmacies. It is not legal to sell or to buy a licence; a licence may, moreover, be withdrawn by a law court in cases of grave misdemeanour. In Berlin, which has about 4 million inhabitants, there are only 380 licensed pharmacies. This number would be inadequate were there not an unlimited number of druggists, who, however, are not allowed to make up prescriptions or to sell poisonous drugs.

Medical Lectures for Working People.

Laymen frequently complain of medicine being a science which has but little connexion with the nation. This view is, however, erroneous, as shown by the fact that eminent medical men have accepted an invitation of the trade unions of the great industrial city of Essen to deliver lectures to their members. Among the lecturers are Prof. Sauerbruch, of Munich, on the surgical treatment of tuberculosis; Prof. Rubner, of Berlin, on fatigue; Prof. Thomas, of Leipzig, on the self-government of the human body; Prof. Krehl, of Heidelberg, on the prophylaxis of infectious diseases; Prof. Aschoff, of Freiburg, on the value of autopsies and of experiments on animals for the public health; and Prof. His, of Berlin, on the circulation of the blood and its derangements. The first lecture, delivered by Prof. Bier, of Berlin, on the importance of physical exercises for the prevention of tuberculosis, was very well attended. The scheme of the lectures is a good one, and will certainly contribute to inform the working people of the value of medical researches for their health. The series was opened by an introductory speech from the Chancellor, Dr. Luther, formerly mayor of Essen.

The Institute for Tropical Diseases.

The Institute for Tropical Diseases and Tropical Hygiene in Hamburg recently celebrated its twenty-fifth anniversary, representatives of the Government, the city of Hamburg, and of the medical profession being present. The foundation of the Institute was suggested by the late Prof. Koch, and it was first planned that its seat should be at Berlin, and that it should be attached to Prof. Koch's Institute for Experimental Medicine. It was, however, decided that Hamburg was preferable, because in that great port where seamen from every part of the world meet there is a greater opportunity for the study of tropical diseases and the treatment of patients. The first home of the Institute proving too small, new premises were built and opened in 1914. The premises consist of several buildings. In the main building there is the office of the medical officer of the port of Hamburg, to whom tropical diseases are notified by ships entering the port and who can therefore at once direct patients to the Institute. There is a museum of tropical hygiene, a laboratory to accommodate 50 students, and a library of 20,000 volumes, being the most complete on that subject in Germany. An animal station is connected with the laboratory, where the animals are observed after experiments performed on them. The hospital attached to the Institute has 70 beds, intended for seamen of every nation, and for Germans who have resided in tropical climates. Hitherto about 1000 medical men have worked in the Institute, and about 600 scientific publications have been issued under its auspices. It is a matter of congratulation to the city of Hamburg, which finances the Institute, that the work has been maintained even during the hard times of the inflation. In connexion with the jubilee the Society for Tropical Medicine held a meeting, Prof. Nocht, of Hamburg, being in the chair. Prof. Plehn, of Berlin, formerly of East Africa, read a paper on the development of blackwater fever. Prof. Fülleborn, of Hamburg, gave a report on researches into ascaris infection, and described the complicated mode of entry of the larvæ into the host through the intestines and the lung to the stomach, where the larvæ develop as worms. Dr. Winkel, of Java, Dutch East Indies, gave a report of the salvarsan treatment of frambœsia. By a few injections the disease is, as a rule, cured. Prof. Ziemann reported on a disease known in the tropics as gangosa, somewhat resembling frambœsia. Dr. Hoppenhauer, of Tübingen, praised the results obtained by the treatment of dysentry by yatren, which he described as the best remedy in acute and chronic cases. Excellent results have been reported from the Congo, from the British and the Dutch East Indies, from Japan, and from South America by many authors, who all agree with the extremely good action of the compound. Dr. Werner, of Berlin, spoke on the five-days' fever (febris quintana), a disease which had been observed during the war in the Balkans. Among other papers read before the congress was one by Prof. Thiel, of Leyden, on anopheles; one by Prof. Mühlens on his travels through South America for the study of malaria; and one by Prof. Zschukke on the diseases in Central America. The meeting was attended by 200 medical men who had had experience in tropical diseases.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following health statistics for Liverpool and Leeds show a great similarity. Liverpool has a higher birth-rate, while Leeds shows higher cancer and childbirth mortality. In Liverpool the childbirth death-rate is generally low, perhaps owing to the excellent lead that has been given for many years by the Ladies' Charity.

Name of city.	Estimated mid-year population (R.-G.).	Birth-rate.	Death-rates per 1000 of the population.				Death-rates per 1000 births.		
			All causes.	Tuberculosis.	Cancer.	Resp. diseases with influenza.	Neonatal mortality.	Infant mortality.	Maternal mort. from childbirth.
Liverpool ..	836,396	24·6	13·6	1·52	1·12	3·7	35	103	3·0
Leeds	471,600	18·1	14·3	1·40	1·35	3·8	39	108	3·8

Liverpool.

Dr. A. A. Mussen, the present medical officer of health, and Dr. E. W. Hope, his predecessor, produce a joint report. Only one case of small-pox occurred during the year, and about 75 per cent. of the child population are successfully vaccinated. The results of an inquiry suggested that a considerable amount of vaccination of unvaccinated children is also done within the school period. Six cases of anthrax were reported during the year. Two of the patients handled wool, three handled hides, and one looked after a machine for crushing bone. Up to 1924 nearly all the cases of enteric fever in Liverpool have been caused by *B. typhosus*, but in that year there were 24 cases caused by *B. paratyphosus*, besides 36 caused by *B. typhosus*. Most of the paratyphoid cases occurred in April and May and they had an unusual sex and age distribution. Females and persons under 15 were chiefly affected, and as none of the usual food sources of typhoid fever could be traced, it is deduced that the agent responsible is widely used but not heavily infected, and is more indulged in by children than adults.

There were 230 notifications of encephalitis lethargica compared with 111 in the previous year. The diagnosis was revised in 33 cases after admission to hospital in favour of tuberculous meningitis (eight cases), enteric fever (three cases), pneumonia (four cases), or other conditions, but there remained 189 cases with a case fatality of 10·6. The case fatality in 1923 was 32·4, and it is suggested that the decrease is partly due to mild cases being recognised. Up to the autumn of 1922 lethargic symptoms were predominant, during 1923 cerebral irritation became a more prominent symptom, and in 1924 there was a tendency to revert to the lethargic type. Prior to 1923 the disease occurred in groups with no direct association of cases, during 1923 it was widespread in the city and neighbourhood, in 1924 the area chiefly affected was a broad band of city and suburbs. Half of the 1924 cases were under the age of 20. Before this age sequelæ are commoner, whilst the mortality increases with advancing age. The Liverpool experience is exceptional in that the infectious nature of the disease is clearly demonstrated. In about 18 per cent. of the 1924 cases, and in 9 per cent. of the 1923 cases, a possible connexion with a preceding case was made out. The incubation period is usually from a week to a fortnight. A diagram shows that encephalitis and influenza are not as a rule prevalent together; but in 1924 epidemics of the two diseases occurred simultaneously. Inquiries about the condition of 94 survivors under 16 years of age showed that 37 had made a complete recovery or were but slightly affected. Of the remaining 57, 37 were attending elementary schools, 9 were absent from school, 3 had left school, 4 were in reformatory schools for delinquency, 2 in special schools, and 2 in asylums. Among the 57 the most frequent condition was alteration of the sleep rhythm, which was usually associated with a want of self-control and in extreme cases with moral imbecility. The admission of these children to asylums is not recommended, for recovery may still be possible; and it is suggested that an attempt should first be made to educate them in special classes, and that, if this fails, a residential institution may have to be considered. In view of the definite infectivity of the disease, school-children from infected houses are excluded from school for a period of three weeks.

A chart shows the death-rate in Liverpool per 100,000 from diabetes for each quinquennium since 1890. During 1890–94 the rate was 3·8, and during the next three quinquennia it was 5·3, 6·5, and 8·4. During 1910 to 1914 it was again 8·4; in the war quinquennium it fell to 7·4, and during 1920–24 it rose to 8·6. During the first six quinquennia about 120 males died, compared with 100 females, but in the last quinquennium only 75 males died, as against 100 females, and it seems conceivable that this alteration is due to insulin having a more marked effect in males. A satisfactory scheme is now in operation for dealing with all classes of blind persons, and the city council has passed a resolution recommending all corporation committees to give special consideration to the workshops of the blind when making contracts for articles such as brushes and mats. The Carnegie Welfare Institute is proving a most valuable addition to the maternity and child welfare scheme, and the present report contains photographs and a plan of this new building. Out of 20,599 births, 13,270 were attended by practising midwives and 1501 by the midwives of the staff of the Ladies' Charity; 398 still-born babies were examined by the city bacteriologist, of which 26 (6½ per cent.) were reported as probably syphilitic. There were 690 notifications of ophthalmia neonatorum during the year with three cases of damaged sight among the survivors. X ray examination has been much used for the diagnosis of tuberculosis, and the satisfactory results are shown by the facts that whilst out of 1806 admissions to sanatoria, only nine patients were subsequently considered to be non-tuberculous; cases diagnosed as negative seldom return to see the tuberculosis officer. The Seamen's Dispensary was opened in January, 1924. Though it is intended primarily to deal with venereal disease, seamen will be able to obtain advice there for other ailments, including tropical diseases, before being referred to other institutions. The number of new cases of venereal disease dealt with at the dispensary during 1924 was 428. A few years ago the Welsh sheep farmers suffered serious loss from the condemnation of their mutton at the Liverpool abattoir owing to the effects of liver fluke. The efforts of the Board of Agriculture to eradicate the disease in North Wales by spraying the pastures and brooks with chemical substances intended to destroy the water snail, which is the intermediate host of the liver fluke, have apparently been successful. The Welsh sheep now show remarkable freedom, though the Irish and Scotch sheep are severely infected. Of 3740 cows in the city cowsheds in 1924, 26 were found with tuberculosis of the udder. The bacteriological report on the examination of milk samples taken from bulk does not indicate that tubercle of the udder is getting less but rather that it is on the increase. Of samples of country milk examined during the eight years 1913–20, 6·4 per cent. were tuberculous, while for the four years 1921–24 the figure was 10·1. During 1924, 57 out of 549 " bulk " samples of country milk and 22 out of 232 " bulk " samples of city milk proved tuberculous (10·4 and 9·5 per cent. respectively).

Housing is still a serious problem in Liverpool, and the houses provided since the war have neither overtaken arrears nor met the needs of the growing population. An estimate is put forward that Liverpool is worse off now than it was at the end of 1914 by rather more than 10,000 houses.

Leeds.

Dr. J. Johnstone Jervis records the prevalence of influenza of a peculiarly malignant form at the beginning of the year. The deaths registered numbered 404, and the death-rate for the year (0·86) was the highest since the influenza years of 1918–19. During the epidemic the infant mortality-rate went up with a bound, and in the third week of February reached the phenomenally high figure of 321. The general death-rate rose to 38·4 in the first week of March and was 35·9 and 26·1 in the two subsequent weeks. Normal figures were reached about April. A good many cases ended fatally within 48 hours of the first symptoms. Some cases were removed to hospital, but as a rule too late to be of any use, and Dr. Jervis has not much faith in hospital removal for influenza complicated with pneumonia. He refers to the inadequate hospital accommodation provided for the city for non-infectious diseases. All the voluntary institutions have long lists of patients awaiting admission, whilst the Poor-law infirmaries are partially empty. The way out of the difficulty, says Dr. Jervis, is obviously to open the doors of the Poor-law infirmaries to the whole community. Atmospheric impurity in Leeds is getting less. The percentage of factory chimneys emitting dense smoke for more than three minutes during an hour's observation is also decreasing. Thus, the percentage from 1920–24 has been 12·4, 8·6, 7·1, 3·3, and 1·7. During these five years over 25,000 observations of one hour each have been made. Among 2063 cows in the city 13 cases of tuberculosis were found, in 5 of which the udder was affected, whilst the remaining 8 had generalised tuberculosis. There has been little advance in cleanliness of methods.

There were only seven (mild) cases of small-pox notified with no deaths, and Leeds also showed less increase in encephalitis lethargica than many other towns. The cancer death-rate was the highest ever recorded. The health committee have set up a special committee to inquire into the local incidence of the disease. Considerable progress has been made in the reorganisation of the tuberculosis scheme. A whole-time clinical tuberculosis officer has been appointed, and a sanatorium school for children with signs of early disease of a non-infective type has been opened at the Hollies, Weetwood. The provision of sanatorium accommodation for women and children is a matter of extreme urgency. Dr. Jervis is also of opinion that no tuberculosis scheme can be considered complete which does not find suitable remunerative employment under favourable conditions for the men and women who undergo sanatorium treatment. 993 new cases attended the 14 antenatal centres, and there were 8558 births. About 20 per cent. of the total births took place in institutions or nursing homes. The corporation have made arrangements for the provision of maternity beds at the three Poor-law union infirmaries. This scheme came into operation on April 1st and was not much used during the year. It is, however, expected that when the excellence of the accommodation becomes known the facilities will be utilised to the full. A special block at the city hospital has been opened for cases of puerperal sepsis. Cases of septic abortion and abscess of the breast will also be admitted.

The health committee have spent considerable sums during the year in providing convalescent home treatment for mothers and babies. The housing problem is as pressing as ever. Dr. Jervis points out that about two-thirds of all the deaths occur in back-to-back houses. He is unable, however, to give separate figures for the ancient and modern back-to-back houses. The modern ones, he says, are little different from " through " houses in healthiness, and this statement appears to be borne out by the figures of deaths, seeing that 77,790 of the 115,289 houses in Leeds, or very nearly two-thirds, are of the back-to-back type.

MENTAL HOSPITAL REPORTS.

Dorset finds that its mental patients are steadily increasing in number, especially the women, but *Dorset Mental Hospital* has still some of its 950 beds vacant. The recovery-rate for the year was 43 per cent. and the death-rate 7·44 per cent., a figure which, the superintendent complains, in common with so many of his colleagues, might be lower if the infirmaries were prepared to relieve the asylums of their unnecessary burden of senile cases. There was an epidemic of scarlet fever, introduced by a nurse, and over 100 persons were affected by a mild influenza epidemic in the spring. A visiting surgeon has recently been appointed and his services will be much appreciated. The dental surgeon has seen 193 patients during the year. Recent structural improvements include an automatic telephone system, a steam disinfector, and the installation of four special baths for continuous treatment. The hospital now has 70 additional acres of farm land which will be extremely helpful to the patients and organisation staff. Dorset county was one of the first to develop the important out-patient aspect of the mental work. The clinic at the Dorset County Hospital continues to flourish. The number of new cases is increasing and many patients discharged from the hospital report from time to time for advice or treatment. This is clearly a most valuable function of the clinic. The commonest type of out-patient is the anxiety neurosis. Parole is granted to 33 patients outside the hospital grounds and to 81 on the estate, and there are open-door wards and a club ward. The laboratory has been busy with routine examinations and three typhoid carriers have been detected, with the result that there has only been one case of typhoid in the hospital, whereas it used to be endemic. Investigation has been made into the urea-content of the blood in epilepsy.

Wilts County Mental Hospital has over 1000 patients under care. The recovery-rate was 27·7 per cent. and the death-rate 7·1 per cent. 44·4 per cent. of those who recovered were admitted in their first attack within three months of its onset. Almost all those discharged had a probationary period on trial and several of these were helped with a money grant. The general health during the year was good, but there were 12 cases of dysentery and two of typhoid fever, which has not yet been traced to its source. A cinematograph apparatus has been installed. The patients are encouraged to wear their own clothes, though at present only a small proportion are doing so. At present there is no laboratory.

Derby Borough Mental Hospital has had a recovery-rate of 10·7 per cent. for men and 53·3 per cent. for women, among its 400 patients. The death-rate was

8·6 per cent. and post-mortem examinations were held on all but one of the fatal cases. The general health of the patients has been good except for an epidemic of influenza. The recommendations of the "dietary" report of the Board of Control have been adopted to a large extent. Of the nursing staff, 63 per cent. on the male side and 24 per cent. on the female side hold the certificate of the M.P.A., a much higher figure than that for the country generally. Parole is allowed to a number of patients, and money allowances were granted to a few of those sent out on trial. There is at present no visiting specialist staff, not even a dentist. The borough has 42 certified mental defectives in its charge and, like so many other places, has continued difficulty in finding accommodation for urgent cases.

Roxburgh District Board of Control has published an annual report to May last. It maintains 350 patients in the asylum at Melrose. The female admissions are usually greater than the male, but this year they have been more than double. The recovery-rate was 31·3 per cent. and the death-rate 7·2 per cent. Influenzal attacks and a few cases of diphtheria were the only infectious diseases. The source of the diphtheria could not be traced. For two years in succession there have been no failures among the nurses sitting for the final examination of the M.P.A. The number of voluntary boarders shows a satisfactory increase.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED Nov. 7TH, 1925.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 56 (compared with 98 last week); scarlet fever, 2537; diphtheria, 1105; enteric fever, 69; pneumonia, 1016; puerperal fever, 51; cerebro-spinal fever, 11; acute poliomyelitis, 9; encephalitis lethargica, 40; dysentery, 8; ophthalmia neonatorum, 117. There were no cases of cholera, plague, or typhus notified during the week.

Deaths.—In the aggregate of great towns, including London, there were 3 deaths from enteric fever, 31 from measles, 14 from scarlet fever, 11 from whooping-cough, 31 from diphtheria, and 59 from influenza. In London itself there were 9 deaths from diphtheria and 26 deaths of infants under 2 years of age from diarrhœa and enteritis.

MEDICINE AND THE LAW.

Paraldehyde as a Dangerous Drug.—Mistaken Identity.

RECENTLY an inquest was held at Hammersmith upon the body of a man whose death was attributed by medical evidence to pneumonia accelerated by the use of paraldehyde. The deceased, it seems, had been addicted to cocaine until he had become the object of police-court proceedings under the Dangerous Drugs Acts; he had then turned to paraldehyde which, as a medical witness observed, can at present be bought without difficulty and should be placed under severe restrictions. The coroner, who recorded a verdict of death from misadventure, confirmed this opinion and remarked that the evidence showed that restrictions should be placed upon the sale of all drugs of a hypnotic nature.

There was one remarkable feature of the case. The dead man, it seems, used the name Geoffrey Wentworth Malim. The Medical Directory contains an entry of a doctor of that name. It thus happened that, when the inquest was opened, it was assumed that the body was that of Dr. Malim, and more than one newspaper report appeared under the headline "Doctor as Drug Victim." The inquest was adjourned. When it was resumed the West London coroner announced that it had now become known that the dead man's proper name was Samuel Neville Appleton. The real Dr. Malim had written to say that Appleton had used his name frequently, and had caused him much trouble by running up bills in that name.

The incident has two important aspects. There is the aspect personal to Dr. Malim, who is entitled to the amplest amends which publicity can make for the injury done to him by the dead man—an injury for which the law affords little remedy. Scotland Yard, it appears, had been notified by Dr. Malim four months earlier that this imposture was being carried on. It is unfortunate that the police authorities, through whom (in part, at any rate) the identity of Appleton was established at the inquest, should not have found themselves able to take action at the time. The other aspect of the case is general. The proceedings were reported, as already stated, under headlines which inevitably suggested that a member of the medical profession had abused the facilities which have been, and must be, entrusted to medical practitioners in respect of dangerous drugs. Three years ago the Home Office inserted in the Dangerous Drugs Regulations the sentence "the prescription shall not be given for the use of the prescriber himself." Considerable feeling having been aroused in the profession, the offending sentence was formally rescinded six months afterwards. Lest there should still be a tendency to distrust doctors in such matters, it is the more essential to emphasise the fact that the recent case was not that of a "Doctor as Drug Victim."

The Services.

ROYAL NAVAL MEDICAL SERVICE.

THE following appointments have been notified:—Surg. Comdrs.: C. G. Sprague to the *Emerald;* R. Kennedy to the *Ark Royal;* H. D. Drennan to the *Yarmouth* (on completing) to the *Hawkins*, and as Fleet Medical Officer; and W. L. Hawkins to the *Yarmouth*, for passage home. Surg. Lt. W. Young to the *Ark Royal.*

Surg. Lt. L. P. Spero, R.N.V.R., to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

Maj. H. B. Kelly to be Lt.-Col., vice Lt.-Col. B. A. Craig to ret. pay.

Maj. M. Keane retires on retd. pay and is granted the rank of Lt.-Col.

Capt. R. I. Sullivan is secd. for service under the Colonial Office.

J. M. Johnston to be temp. Lt.

SUPPLEMENTARY RESERVE OF OFFICERS.

Lt. G. Marshall, late Temp. Lt., R.A.M.C., to be Lt.

TERRITORIAL ARMY.

Capt. J. L. Johnston (late R.A.M.C.) to be Lt., and relinquishes the rank of Capt.

Capt. A. R. Ross to be Div. Adjt., 56th (1st London) Div., T.A., vice Capt. G. G. B. Holroyde, R.A.M.C., who vacates that appt.

Capt. J. H. Fletcher, R.A.M.C., to be Div. Adjt., 48th (South Midland) Div., T.A., vice Capt. F. G. L. Dawson, R.A.M.C., who vacates that appt.

Supernumerary for Service with the O.T.C.: Lt. L. B. Maxwell to be Capt.

General List: 2nd Lt. A. Barr (late R.G.A.), to be Lt.

ROYAL AIR FORCE.

Medical Branch: Flight Lt. T. J. Thomas is promoted to the rank of Squadron Leader.

Flight Lt. (hon. Squadron Leader) E. A. Aldridge relinquishes his temporary commission on ceasing to be employed.

Flying Officer H. J. Henderson (temp. Lt., Dental Surgeon, General List, Army) relinquishes his temporary commission on ceasing to be employed.

INDIAN MEDICAL SERVICE.

Revised rates of furlough pay in India for regular executive officers of the I.M.S. in military employ have been announced. Maj. W. G. Hingston is appointed Surgeon Naturalist Marine; Maj. G. Covell has been appointed temporarily to the Medical Research Department and posted to the Central Research Institute, Kasauli; Maj. S. S. Sokhey, who was one of the selected candidates for the Rockefeller Foundation Scholarship of 1922–23, has returned to India and has been appointed Medical Officer in Charge of the Biochemical Unit of the Haffkine Institute, Bombay; Maj. R. F. D. MacGregor, on return from leave, has been posted as Agency Surgeon, Bhopal; Col. R. P. Wilson, Acting Surgeon-General, has vacated his seat on the Bengal Legislative Council in favour of Maj.-Gen. R. Heard, who on return from leave has resumed his substantial appointment as Surgeon-General with the Government of Bengal; Lt.-Col. W. J. Powell, Inspector-General of Prisons, acts as Director of Public Health of the Central Provinces in addition to his own duties.

Correspondence.

"Audi alteram partem."

MEDICAL MANIFESTOES.

To the Editor of THE LANCET.

SIR,—During the past ten days I have received circular letters from two medical bodies. Each body proposes to issue a memorial or manifesto. One states that agreement will be assumed unless dissent is made. The other concludes: "If I do not hear from you by return of post I shall conclude that you are willing to allow your name to be published in this connexion." And accordingly the names of non-committed men will be attached to a manifesto to the lay press which begins: "We, the undersigned——." It seems to me that this procedure is wrong, and that if it be allowed medical manifestoes will be treated with contempt.

I am, Sir, yours faithfully,
N. BISHOP HARMAN.

Harley-street, W., Nov. 17th, 1925.

THE SANITATION OF DAVOS.

To the Editor of THE LANCET.

SIR,—As I had the privilege of representing Great Britain—if unofficially—along with Dr. Leonard Hill at the recent climatological congress in Davos, I should like to supplement the account of the climatic advantages of that place, described by Dr. Hill and Dr. Bernard Hudson in your issue of Oct. 24th, by a few remarks on its sanitation from the point of view of a medical officer of health.

On arriving there on August 13th last I was first struck by the general cleanliness and freshness of the town—a feature which I may say it has in common with most other towns and villages in Switzerland. The streets are wide, clean, well paved and drained, so that rain does not remain long on their surfaces. The hotels, sanatoria, &c., are supplied with the most modern sanitary fittings for baths and lavatories, and would satisfy the most exacting health officer. Somewhere about the commencement of 1900 the whole sewerage and drainage systems were thoroughly overhauled, and with the help of the swift mountain torrents and a good supply of water, both sewers and drains are kept thoroughly and regularly flushed. The drinking water is cool, sparkling, and most refreshing, and comes from gathering grounds in the mountains where risk of contamination is nil.

The most efficient and thoroughly up-to-date piece of sanitation I had the opportunity of examining was the system of collection and disposal of house refuse. In the first place, in 1913 Davos got a special Act of Parliament enabling the town council to acquire land, put up a refuse destructor, and provide for the collection and removal of household dust in suitable movable bins supplied by them. The working charges are provided for by levying a contribution on hotels, &c., according to the amount of household refuse removed. Non-compliance with this Act and the regulations made under it is punishable by a fine of from 5 to 50 francs.

The bins are cylindrical in form, the diameter at the top being $16\frac{1}{4}$ in., the bottom $15\frac{1}{2}$ in., and the height 2 ft. 8 in. They are constructed of very strong galvanised iron, and have a tightly fitting lid, which *must* be kept closed when the bins are in use. In summer when full they are placed on a lorry which calls for them, and in winter these lorries are replaced by sledges. They are then driven to the railway station, placed on a special wagon and sent to the refuse destructor, which is attached to the gasworks in Laret, some six English miles away.

From the railway there is a special siding running into the destructor where the dustbins are unloaded. The destructor is of the high temperature type with forced draught, and after removal of the lid the bin is placed in a special mechanical contrivance in which it can be easily inverted, and by pulling out a damper which replaces the lid the whole of the contents fall through an opening of the same diameter as the bin, straight into the furnace. In this process not a particle of smoke or dust can escape while the bin is being emptied. The bin is again turned upright, removed from the holder, and placed in a washer, where it is thoroughly cleansed by boiling water. This is provided by a steam boiler attached to the furnaces. The whole destructor is really part and parcel of the gasworks, and the steam raised is used in the first place for driving the machinery of the destructor, and the surplus is passed on to the gasworks to assist in driving their machinery. If there is insufficient steam to drive the destructor the deficit comes from the gasworks. The cleansed bins are returned to the town as required, and a sufficient stock is kept by the council to leave empties as the full ones are removed.

Complete combustion of the refuse is the first consideration, and suitable mechanical arrangements are made for separating the clinker from the lighter materials, as well as dealing with gases. The main point seems to me is that the dust once it is deposited in the bins only leaves them to go direct into the furnace, and, therefore, no opportunity is given for fly breeding or nuisances being created in its handling or disposal.

I am, Sir, yours faithfully,
R. KING BROWN, M.D.

Bermondsey, Nov. 7th, 1925.

PARACUSIS WILLISII.

To the Editor of THE LANCET.

SIR,—Since Thomas Willis called attention to the phenomenon in the seventeenth century paracusis has been regarded as symptomatic of oto-sclerosis unaccompanied by labyrinthine involvement. The phenomenon is of value in diagnosing fixation of the stapes and in judging the prognosis of the case. The fact that the low-tone limit is raised while high tones are unaffected in purely obstructive deafness suggests that the ossicular chain is not a mere passive pathway for the conduction of sound waves, but plays an active part in rendering low musical tones perceptible. The individual with normal hearing regulates the force of his voice by his own perception; he instinctively raises his voice in a noisy circle. This is a striking example of Sherrington's "auditory and speech reflex." An oto-sclerotic, on the other hand, does not raise his voice in a noisy railway carriage, but persists in talking in a low well-modulated voice hardly audible to a companion. He maintains this characteristic tone whether talking in a noisy circle or a quiet room. Evidently the coarse vibrations of long amplitude produced by extraneous noises fail to stimulate the perceptive mechanism of an oto-sclerotic.

The oto-sclerotic, then, has certain advantages over one who has normal hearing. The coarse vibrations of long amplitude produced by railway trains and the like fail to reach his consciousness; he calmly concentrates on his friend's talk. Knowing his disability he pays greater attention to the conversation. The normal individual instinctively raises his voice in a noisy place to the great advantage of his oto-sclerotic friend, who is not disturbed by the extraneous noises quite to the same extent. Further, the man knowing that he is talking to one who is hard of hearing the normal individual sympathetically raises the force of his voice. All these factors, working together, enable the oto-sclerotic to follow conversation in a noisy circle with ease.

I am, Sir, yours faithfully,
J. M. DAMANY, M.B., B.S.

Oxford-road, Putney, S.W., Nov. 17th, 1925.

FOOD EDUCATION SOCIETY.

To the Editor of THE LANCET.

SIR,—Our late premises are coming down, but we have been fortunate in obtaining an office in the new Mary Sumner House of the Mothers' Union, between whom and ourselves there has been in the past cordial coöperation. The expenses of removal and furnishing and of notifying the press, members, and correspondents of our change of address are necessarily considerable. The Committee have accordingly resolved to raise, as in 1909, a special fund for the purpose. Moreover, in view of the gratifying testimony received from all parts of the world, including the formation of a branch for the State of Victoria, the Committee feel that the moment is opportune for an effort to free the society from a deficit—materially reduced, but still standing at £350—which is mainly the result of its labours for the prevention of dental disease. The service to the nation thus rendered has been recognised by the Dental Board of the United Kingdom (a Government body), on whose late advisory committee the society was represented, as likewise by the President of the British Dental Association and by Sir George Newman.

The society is also urgently in need of funds to reprint such favourites as "Economical Dishes for Workers" (over 100,000 sold), "Diet for Brain Workers," "Sugar, Why Worry About It?" "The Feeding of Nurses" (edition of 1000 exhausted), and to issue fresh publications, with reports of its many-sided activities.

Donations should be addressed to the Hon. Treasurer, Sybil, Viscountess Rhondda, at the undermentioned address.—We are, Sir, yours faithfully,

HARRY CAMPBELL,
Chairman.
H. BALDWIN,
Vice-Chairman.
SYBIL RHONDDA,
Hon. Treasurer.

24, Tufton-street, Westminster, S.W. 1.,
Nov. 13th, 1925.

PRE-CANCEROUS STATES.

To the Editor of THE LANCET.

SIR,—May I be permitted to supply a few additional details to the condensed report of my remarks in the course of the discussion on pre-cancerous states reported in THE LANCET of last week (p. 1022). When dealing with the changes found in chronic mastitis, and referring to the part played by the basement membrane in guiding us to form an opinion as to whether carcinoma is present in certain doubtful cases, I said :—

> "In certain cases it will be found that—perhaps in one small area—this smooth regular band or limiting membrane is absent, the clumps of epithelial cells are lying loosely in cavities and not attached to the walls . . . the border-line has been crossed and carcinoma is present. . . . In such examples as I have endeavoured to outline above in which the main part of the section consists of inflammatory tissues and only a small portion is carcinomatous, it appears to me quite evident that inflammation has preceded the new growth. Carrying the argument a step further—the above evidence points clearly to the great probability that in many instances a breast affected with chronic inflammation is in a pre-cancerous state."

It will be seen therefore that my view is that in *many instances* breasts affected with mastitis are in a pre-cancerous condition; but, if we carry things back too far, we shall be placed in the position of having to state that everyone affected with some trifling inflammatory affection is in a pre-cancerous condition, which is absurd.

As to papillomata, it is obvious that when invasion of the deeper tissues by the superficial cells has taken place, carcinoma is already established. It is the presence in some papillomata of groups of squamous cells at the base lying in masses of small round inflammatory cells that suggests a pre-cancerous stage.

I am, Sir, yours faithfully,

Royal Northern Hospital, Nov. 16th. ERNEST H. SHAW.

THE CINEMA IN NEUROLOGY.

To the Editor of THE LANCET.

SIR,—The writer of the annotation with the above title, which appeared in your issue of Nov. 7th, is in error when he states that the films exhibited in Paris by Dr. S. Philip Goodhart "are the only ones in existence dealing (from the technical aspect) with nervous disease." On the contrary, films of an analogous kind have frequently been made and used in this country, as is well known. As a single instance, I may mention those made by Dr. A. F. Hurst during the war and dealing largely with functional nervous disease. When delivering the Croonian lectures last summer before the Royal College of Physicians I exhibited two long films devoted entirely to the technical side of some neurological conditions, and included in them were sections made by the slow-motion camera.

I am, Sir, yours faithfully,
S. A. KINNIER WILSON.

Harley-street, W., Nov. 16th, 1925.

SPIRITUAL HEALING AND MODERN MEDICINE.

To the Editor of THE LANCET.

SIR,—Will you allow me to disclaim, in the most formal fashion, any but a few slight correspondences between the remarks attributed to me in THE LANCET of last week and those which I did make at a meeting of the Hunterian Society on Nov. 9th. My remarks were read from a typescript, now before me, which, after the meeting, was in the hands of the reporters present.

I understand, however, that the impossibility of forwarding a proof accounts for a version which substitutes the words *medical* for *metaphysical*, and *material grounds* for *ratiocination*, at the same time making use of expressions and phrases never employed by me during the debate. I did not say that psycho-analysts had shown that states of mind must be held responsible for many organic conditions. I did say that, as a result of the work of the Viennese psycho-analysts, it was beginning to be believed by many that states of mind must be held responsible for many bodily disorders and for at least the functional beginnings of organic disease. The point of a remark made to me not very long ago by the late Dr. Sidney Martin is completely destroyed. The old curé in "Maria Chapdelaine" (and no old French physician) said that while the doctors do what they can, only God understands diseases. He did not say that only God understands humanity. I said that longevity is marked and the standard of physical health extremely high amongst the Quakers; I did not say that the standard of health was nowhere so high as amongst the Quakers.

More importantly: I did not say that a belief in miracles was essential to the doctor's art. I said that the conception of miraculous healing, whatever the historical evidence, is as necessary to our philosophy of the healing art as is our knowledge of the reparative power possessed by the salamander or newt. Above all, far from saying that the miracle of healing represented the manifestation *in ourselves* of a certain power, I said that it represented, for the physician, the manifestation, *in the Absolute*, of a certain power!

There are many other errors and misleading paraphrases of my remarks in this report; may I beg, therefore, for lenient consideration at the hands of your readers?

I am, Sir, yours faithfully,
F. G. CROOKSHANK.

Wimpole-street, W., Nov. 16th, 1925.

*** Our reporter's claim to have given a very fair account of Dr. Crookshank's general attitude is supported by others who were present.—ED. L.

DEFECTIVE ILLUMINATION IN RELATION TO EYESIGHT.

To the Editor of THE LANCET.

SIR,—In an annotation with this title in your issue of Nov. 7th, referring to a bulletin issued by the United States Public Health Service, appears the rather contradictory comment :—

> "We find no evidence that defective illumination is in itself a cause of permanent injury to the eyesight. . . On the other hand, there is plenty of evidence . . . that work for the eyes under defective illumination involves fatigue, and that this may cause permanent injury to 'weak' eyes."

Is this not rather quibbling with the original cause ? It is quite possible that the only effect of defective illumination on good normal eyes might be fatigue, but even fatigue alone connotes lowered resisting power, and again how many eyes are normal ? There is not an atom of doubt that defective illumination does accentuate eyestrain, such eyestrain being possibly produced by a very small amount of astigmatism or anisometropia or imbalance (not unbalance) of the muscles. The end-result of such a condition may show itself as (*a*) local disease of the eyes owing to lowered resistance to germs, some of which are always present producing some form of conjunctivitis, or even deeper trouble, such as cyclitis or even iritis ; (*b*) general effects of eyestrain, due to loss of nerve energy, manifesting itself in headaches, insomnia, indigestion, &c. I look upon the recent improvement in the illumination of public buildings, offices, &c., as one of the very important methods of "preventive medicine."

I am, Sir, yours faithfully,
ERNEST CLARKE.

Chandos-street, W., Nov. 16th, 1925.

⁂ The harmfulness of defective illumination is agreed ; it is surely of more than verbal interest to determine precisely how the harm is done. We do not share Mr. Clarke's objection to the American use of the word unbalance.—ED. L.

X RAYING OF TEETH.

To the Editor of THE LANCET.

SIR,—The letter from Sir Gould May in your issue of Oct. 31st raises two important points, on which, as a dental surgeon, I should like to comment. The two points are these : the value of radiographs of the teeth and reports based on the radiographic findings, and the significance of dental sepsis as a factor in general disease.

Concerning the first. Sir Gould May suggests very plainly that either radiographs of the teeth and jaws have little diagnostic value or else that the reports made by radiologists are made with so little judgment and knowledge that no reliance can be placed on them. I do not suppose that it is intended, but the letter could be read as though it were a reflection on the bona fides of radiologists. A dental radiograph, like that of any other part, is a shadow photograph in two dimensions of solid structures. Fallacies may arise which are due to distortion, though they may simulate a pathological condition, such as the appearance of the mental foramen which has before now been mistaken for apical rarefaction. There are also fallacies due to the technique which can mislead the unwary. A competent radiologist should, however, be able to eliminate such errors, and I doubt if many reports contain inferences which are based on an actual misinterpretation of the films. The report which accompanies the radiograph is not a diagnosis of the pathological conditions of the teeth and jaws, and never can be. It is an aid to diagnosis, and often of great value. Two factors go to the making of a good report of a dental radiograph—a sound technique and a thorough knowledge of the normal anatomy of the teeth and jaws, as well as of their pathology. Radiographs may be taken by radiologists who are medical practitioners, by dentists who usually limit themselves to dental radiology, though by training and usually by experience they are familiar with dental surgery in its clinical aspects ; and by radiographers who have no medical qualification and whose knowledge of the anatomy and pathology of the teeth and jaws cannot be very extensive, though their technical achievements are frequently of a high standard. All three may take dental radiographs of great technical excellence, though candour compels me to state that not infrequently I have seen dental films taken by general radiologists so distorted that no report of any value could possibly be based on them. (This is not to be taken as a reflection on radiologists or as suggesting that only dental radiologists should take dental films.) Reports on films, however, vary much in their value. To the dentist familiar with the teeth they may add considerably to the value of the films or they may add nothing. Obviously the greater the knowledge of the anatomy and pathology of the teeth on the part of the radiologist, the better is his report likely to be. To the dentist the radiograph will always be of more importance than the report, for he should be in a position to interpret the films for himself, though I cannot agree with those dentists who tacitly regard the radiologist's report as unnecessary and without practical value.

Sir Gould May infers that the reports invariably state that disease is present. Does he think that radiologists have fallen into the habit of doing this as a routine, whether the films justify it or not, much as some osteopaths are said always to find displacement of the vertebræ ? It must be remembered that when a patient is sent to have radiographs taken of the teeth there is generally primâ facie reason to suppose some degree of dental infection. But the real point is the degree of value attaching to a radiograph. It is an aid to diagnosis only. A diagnosis of the dental condition should be based on *all* the data available. It involves a clinical examination by a dentist with all the methods at his disposal. Among these radiography is of considerable value, but only when taken in conjunction with the clinical examination. Every dentist knows that a careful examination of the mouth may reveal more than a radiograph, though conversely the latter may reveal what a clinical examination is unable to detect. But often radiography is used as the only method of diagnosis, and hence, I believe, arise the difficulties to which Sir Gould May alludes.

It is becoming an increasingly common practice for doctors to send their patients direct to the radiologist for a film of the teeth. Armed with the radiologist's report, plus what he may discover (or imagines he discovers) by a casual inspection of the mouth, he will often condemn the teeth in advance and then send the patient to a dentist with a statement of what he considers should be done. I submit that this is the incorrect procedure, and must inevitably lead to blunders. The proper way would be for the doctor, who has reason to think that the patient's dental condition may be related to some ailment elsewhere, to send the patient first to his dentist with a request that the latter should investigate carefully the dental condition and report thereon to the doctor. The dentist will obviously get all the data available, including so valuable a procedure as a radiograph. His conclusions as to the conditions present, their pathological significance, and the best treatment to be pursued, may not be infallible, but they will be based on all the evidence instead of a part only. The doctor and dentist should work together as members of a team who have the common aim of desiring to better the bodily condition of their patient. This might not be always feasible, but often it could be done and it would be far preferable to rely on the imperfect evidence of radiography unbacked by the all-round examination of the dentist.

As to Sir Gould May's other point, the rôle of dental sepsis in disease, this is a vast subject. Admitting that the hypothesis of focal infection may have been pushed to too extravagant a length by some, yet there is a wealth of evidence to show that dental sepsis is often a potent factor in leading to a widespread train of diseased conditions elsewhere. This in itself is a justification for the interest taken in this subject, though it does not justify a belief that extraction of the teeth is a panacea to be applied in every case of disease elsewhere.

I am, Sir, yours faithfully,
Wimpole-street, W., Nov. 14th, 1925. A. T. PITTS.

To the Editor of THE LANCET.

SIR,—It seems to me the real point at issue is not whether teeth should or should not be examined by X rays, or any other rays, but what use will be made of the information obtained. I have had much to do with Americans; they believe they can see further through a stone wall than most people, and have therefore a strong predilection to prophesy what they think is going to happen, and then to suggest treatment for the disease which will be present later on rather than to consider the complaint before them. In a consultant this power of prevision is invaluable; in the general practitioner it is very dangerous. For simplicity may I illustrate? My wife went to a dentist, who told her she had pyorrhœa and must have her teeth out. I gave her some quinine and sulphuric acid mixture, and sent her back in three months to have a tooth filled, when the pyorrhœa was gone. By all means use all these new powers we possess, but let us not forget to cure the patient. I am astonished at the number of people I meet who have no teeth, and yet are still suffering from the disease for which the teeth were extracted; in some cases simple medical remedies have removed the trouble. Cure of the patient should be our object rather than the diagnosis of disease, which is not always possible and is of little interest to the patient. Diagnosis is of great interest to the doctor, but the extraction of all the teeth is a method of diagnosis which is being carried too far to-day.

I am, Sir, yours faithfully,
Bournemouth, Nov. 16th. C. G. S. BARONSFEATHER.

DIALACETIN IN EPILEPSY.—Dr. C. Worster-Drought writes to correct the dosage of dialacetin in epilepsy contained in his letter which appeared in THE LANCET of Oct. 24th (p. 892). The dose of dialacetin should read: ½ to 1 tablet either at night, or twice daily, and not 1½ gr. as stated. Each tablet of dialacetin contains 4 gr. of allylparacetaminophenol and 1½ gr. of dial. The dose in epilepsy, therefore, is 2¾ to 5½ gr. of the combined substances at night only in nocturnal cases, and twice daily in others.

DONATIONS AND BEQUESTS.—Mr. W. L. Bowles, of Cardiff, has given £1000 to endow a bed at the Cardiff Royal Infirmary to commemorate his seventieth birthday.—Sir Robert Appleby Bartram, of Thornhill Park, Sunderland, has left by will £5000 to the Sunderland Royal Infirmary, and £5000 (additional) to the Sunderland Royal Infirmary for the Children's Hospital.—The West Riding Coalowners' Association has given £25,000 to the Leeds University Appeal Fund.—Mr. E. G. Bates, a former member of the Croydon Council, has given another £1000 for the pension fund for the blind which bears his name. Mr. Bates started the fund in 1919 with £3000, and has added to it since. The capital invested is now £8000.—Lady Rebecca Inglis, of Reigate and Bath, who left estate of £76,301, directed that her jewellery be sold and the net proceeds given to the Throat and Chest Hospital, Golden-square, London. She also left £1000 to the Reedham Hospital for Children, and £1000 to Dr. William Stanley Melsome, her medical attendant at Bath. After other bequests, the residue of her property—which will amount to about £50,000—to be equally divided between St. Dunstan's Hostel for Blinded Sailors and Soldiers, St. George's Hospital, the Middlesex Hospital, St. Bartholomew's Hospital, the Hounslow Hospital, the Reigate and Redhill Hospital, the Royal Blind Pension Society, the Royal Hospital for Incurables, the Orphan Working School, the Infant Orphan Asylum, and the London Orphan School, Watford.—The Refuge Assurance Company, Limited, has sent a cheque for £1000 to the Lord Mayor of Manchester for the Manchester Cancer Research Fund.—A cheque for £1547, the proceeds of a pageant in the Stretford area of Manchester, has been given to the Basford House Hospital, which will be officially opened in March next year.

Obituary.

JUAN GUITERAS.

THE death has occurred in Cuba of Prof. J. Guiteras, an authority on yellow fever and other tropical diseases, in his seventy-fourth year.

PROF. GUITERAS.

Juan Guiteras y Gener was born at Matanzas in Cuba in 1852. After being educated in Cuba he went to the University of Pennsylvania and became M.D. and Ph.D. in 1873. After six years as resident and visiting physician at the Philadelphia Hospital he served for ten years in different parts of America in the Marine Hospital Service. Later he became professor of pathology in the University of Pennsylvania, and in his writings and teaching laid especial and uncommon emphasis on the necessity for looking at pathological processes from a physiological viewpoint. From 1900 onwards he occupied the chair of general pathology and tropical diseases in Havana University, which was the first chair of its kind in America, and in 1909 became Director of Public Health of Cuba and President of the National Board of Health. Guiteras's name is chiefly associated with the campaign against yellow fever. He served as expert adviser in all the epidemics of this disease in the United States since 1881, and it was he who established the importance of yellow fever in children and of benign cases in propagating epidemics. He confirmed experimentally the work of the American Commission on the transmission of yellow fever by the mosquito, and by his active propaganda was able to win agreement for C. J. Finlay's original thesis that the disease was actually transmitted by the bites of the insect. On the staff of General Shafter in the Santiago campaign of 1898 he did good service, and was later given scope for his work under the Yellow Fever Commission set up by the International Health Board of the Rockefeller Foundation. The success of the antimosquito measures which he advocated in Cuba is shown by a decrease in the death-rate from yellow fever in Havana from 81 per 1000 in 1876, for instance, to nil in 1909. Guiteras's attention was, however, by no means confined to yellow fever. He was the first to demonstrate *Filaria bancrofti* in the United States and ankylostomiasis in Cuba. His wide interests and pioneering spirit were shown by his publication, in collaboration with Emilio Martinez, of the *Revista de Medicina Tropical*, which was the first journal of tropical medicine in the continent of America and the second in the world. Prof. Guiteras was a vice-president of the Association of Health Officers of North America, and was also well known in the United States for his interest in the political position of his native island. He was a cousin of the late Dr. Ramon Guiteras, urologist, of New York.

PROF. PAUL HEGER.

A GREAT physiologist and a distinguished Belgian savant has passed away by the recent death, the sad result of a motor accident, of Dr. Paul Heger, professor in the Faculty of Medicine of Brussels University. He was born in Brussels in 1846 and was the son of Prof. Constantin Heger, the friend and teacher of Charlotte Brontë.

Dr. Heger studied medicine in Brussels, and having graduated as M.D. began practice in his native city, directing his attention more particularly to the study of nervous diseases. Amongst his patients was

Mr. Ernest Solvay, and it was largely at his instigation that Dr. Heger relinquished the practice of medicine and resolved to devote himself to physiology. To this end he studied in Leipsic under Prof. Carl Ludwig in the mid-seventies and while there devoted special attention to the perfusion of blood through surviving organs, the particular problem he studied being perfusion of blood through the excised liver to determine to what extent nicotine was absorbed by the liver cells. He was appointed professor of physiology at the University of Brussels, a post which he held until 1907. In 1899 he became director of the physiological institute, which had been erected at the expense of Mr. Solvay in the Parc Léopold—an institute which was a veritable crystal palace, so excellent was the natural lighting. There he and his pupils carried out important work, and many of his researches were published in the *Archives Internationales de Physiologie*, of which he was joint editor with Prof. L. Fredericq, of Liège. On his retirement from the active pursuit of physiology he was appointed honorary professor and president of the University. During the war he took a leading part in the organisation of the medical equipment of the Belgian Army and busied himself in clinical work in the city of Brussels, where he was president of the clinic to which Miss Edith Cavell was attached, and it was he who brought her body to England.

Tall, erect, and of striking personality, Heger was adored by his pupils and assistants and beloved by all who knew him. He had a wonderful and entrancing power of graphic exposition of a subject, the problem in hand seeming to unroll itself with perfect lucidity. When, in 1912, the British Association met in Dundee, Prof. Heger was one of the foreign men of science on whom the University of St. Andrews conferred the degree of LL.D. His wife, who died several years ago, was the daughter of a banker in Brussels. He is survived by a son, who has made for himself a distinguished position in medicine in Brussels, being specially interested in medico-legal medicine.

GEORGE REID, O.B.E., M.D., C.M., D.P.H. Aberd.

Dr. George Reid, formerly medical officer of health to the Staffordshire County Council, died at Stafford on Nov. 7th at the age of 71. He was born in Aberdeen and studied medicine at the University of his native city, graduating M.B., C.M., in 1875, and M.D. in 1881. In 1890 he obtained the D.P.H. Aberd. and was appointed medical officer of health for Staffordshire County Council, an office which he filled for 32 years. Upon his retirement in 1922 he was appointed consultant medical officer to this county, which post he held at the time of his death. Dr. Reid also acted as school medical officer for Staffordshire, medical officer to the Staffordshire, Wolverhampton and Dudley Joint Committee for Tuberculosis, medical officer to the South Staffordshire Joint Small-pox Hospital Board, and examiner in State medicine to the Universities of Cambridge and Birmingham.

At the beginning of Dr. Reid's term of service to the county, Staffordshire had an unenviable record as regards the disposal of human excreta and refuse. Dr. Reid set his face firmly against pollution of rivers and streams, and under his direction the Public Health Committee of the council were successful in persuading the local authorities to disburse nearly two million pounds in schemes to purify the Staffordshire waters. The effect was soon apparent in a reduced typhoid mortality. The experiment in biological treatment of sewage at Hanley attracted much attention, and in 1906 he gave evidence before the Royal Commission on Sewage Disposal with reference to bacterial filtration of sewage, the outcome of which was the erection, at the instance of the Commission, of works to establish Dr. Reid's conclusions. He served also on the Departmental Committee on the use of lead in pottery which sat for two years and reported in 1910. He was early in the field with a scheme for the control of ophthalmia neonatorum. Dr. Reid was the author of a valuable text-book on "Practical Sanitation," which first appeared in 1892, with the primary intention of guiding sanitary inspectors in their work. Successive editions of this book, up to the twentieth in 1921, registered the progressive outlook of a public sanitary department. Dr. Reid was the originator of the Staffordshire or pavilion type of elementary school building, which has been extensively adopted in this country and abroad.

Dr. Reid was at one time president of the Society of Medical Officers of Health, and while holding this office he was associated with Sir Alfred Keogh, then Director-General of the Army, in organising the sanitary services of the Territorial Forces, and he was one of the first sanitary officers to be appointed with the rank of Major. In this capacity he served with the forces at the outbreak of war.

Dr. Reid, who was predeceased about a month ago by his wife, leaves a son and a daughter.

Medical News.

University of Oxford: Lectureship in Embryology.—The University of Oxford has accepted a bequest by Mrs. Constance Jenkinson for the endowment of a lectureship in comparative and experimental embryology in memory of her husband, John Wilfred Jenkinson, of Exeter College, who was killed in the war.

University of Cambridge.—Applications are invited for a Pinsent-Darwin Studentship in Mental Pathology. The studentship is of the annual value of about £200 and is tenable for three years in the first instance. The student may be of either sex and need not be a member of the University of Cambridge. He shall engage in original research in Cambridge or elsewhere, but may, subject to the consent of the managers, carry on educational or other work concurrently. Further particulars may be obtained from the Registrary of the University of Cambridge, and applications for appointment should be sent before Dec. 1st, 1925, to the secretary, Pinsent-Darwin Studentship, Psychological Laboratory, Cambridge. This studentship was founded in 1924 by the benefaction of Mrs. Pinsent and Sir Horace and Lady Darwin for the purpose of promoting research into any problem which may have a bearing on mental defects, diseases, or disorders.—The Managers of this Studentship announce that they have given a grant to Miss M. F. Bridie of Birmingham, in order to facilitate her investigations as to the effect of education among the mentally deficient.

University of London.—The extensions to the Department of Physiology at King's College have now been completed, and were formally opened on Nov. 6th by Emeritus Professor W. D. Halliburton, F.R.S. A reception was held in the new laboratories at which were present many well known physiologists and biologists. The new building will provide facilities for experimental research, for the teaching of advanced practical mammalian physiology, and a professor's room. In addition, the rooms formerly occupied by the Bacteriology Department have been taken over for biochemistry, the provision of animal and polarimeter rooms, and for a staff room and library. The reception was followed by a public inaugural lecture on Science and Culture by Mr. Julian Huxley, who has recently been appointed to the Chair of Zoology at King's College, in succession to the late Prof. Arthur Dendy, F.R.S.

St. Thomas's Hospital.—A lecture on the Earlier Inhabitants of London will be delivered by Prof. F. G. Parsons in the Governors' Hall, St. Thomas's Hospital, at 5 P.M. on Friday, Dec. 4th. During the lecture, which will be illustrated by lantern slides, skulls of the various people mentioned will be shown. Admission is free, without ticket.

Charing Cross Hospital Medical School.—The twelfth biennial Huxley Lecture on Recent Advances in Science in their Relation to Practical Medicine will be delivered by Sir Oliver Lodge, F.R.S., on Thursday, Dec. 3rd, at 3 P.M., in the Out-patients' Hall of the Hospital. Admission free (to medical men), without tickets.

A course of two lectures on the Efficiency of the Heart and its Measurement will be given by Prof. Yandell Henderson (Professor of Applied Physiology in Yale University) in the Physiology Theatre, University College, Gower-street, London, W.C. 1), on Nov. 30th and Dec. 1st, at 4.30 P.M. At the first lecture the chair will be taken by Prof. E. H. Starling, F.R.S. Admission free, without ticket.

The Schorstein Memorial Lecture will be delivered by Sir Humphry Rolleston on Dec. 4th, at 4.15 P.M., at the London Hospital Medical College on Lymphadenoma.

University of Manchester.—The Knight Travelling Fellowship in Psychological Medicine has been awarded to Mr. L. C. Chevens, M.R.C.S. Eng., L.R.C.P. Lond., D.P.H. Manch., assistant medical officer in the Cheshire County Mental Hospital, Macclesfield.

University of Glasgow.—The degree of doctor of medicine (M.D.) was conferred on the following candidates on Nov. 14th :—Hugh S. D. Garven, B.Sc., Ch.B. (with honours) ; Charles M. Smith, M.B., Ch.B. (with high commendation).

Royal Colleges of Physicians of London and Surgeons of England.—As the result of the Final Examination, held from Oct. 6th to 29th, the following candidates were approved in the subjects indicated, but are not eligible for diplomas :—

Medicine.—B. W. Alexander, St. Bart.'s ; R. E. Barrett, London ; H. L. Belcher, Guy's ; E. I. Bieber, Liverpool ; Hilda M. P. Bond, St. Mary's ; R. Broomhead, Leeds ; P. R. Buckton and J. C. K. Chilcott, King's Coll. ; J. H. Chitty, Guy's ; Olive C. Crowley, Charing Cross ; T. W. Davies, Cardiff ; T. E. Davies, St. Thomas's ; Elaine O. H. Earengey, Univ. Coll. ; R. Edmondson, Manchester ; J. A. Eyres, King's Coll. ; R. A. Fitzsimmons, Charing Cross ; Rachel D. Fox, Royal Free ; J. Freudenheim, Charing Cross ; S. C. Gawne, Liverpool ; P. J. Gonsalves, Guy's ; R. M. Greenop, King's Coll. ; H. L. Groom, Univ. Coll. ; A. A. M. Groot, Leiden and Westminster ; B. Guyster, London and King's Coll. ; Kathleen M. Halloran, Calcutta ; K. A. Hamilton, St. Bart.'s ; H. G. Harvey, St. Thomas's; G. F. Henderson, Univ. Coll. ; T. H. Hobbes, St. Bart.'s ; J. E. Howard, St. Mary's ; Mary H. McC. Huggett, King's Coll. ; B. D. Jain, Charing Cross ; Edith M. Little, Katharine G. Lloyd-Williams, and Marjorie Low, Royal Free ; Elsie Lyon and Margaret B. MacDonald, Charing Cross ; G. L. M. McElligott, St. Thomas's ; Evelyn T. D. Maclagan and Mary A. Marshall, St. Mary's ; E. H. Moir and J. E. C. Morton, St. Bart's ; E. R. Owen, Liverpool ; B. N. Pajnigar, London ; J. G. Paley, St. Bart.'s ; H. A. Picton, Birmingham ; D. C. Price, St. Bart.'s ; E. K. Pritchard, St. Thomas's ; Henrietta Procter and Muriel A. Pugh, Charing Cross ; J. H. Randall, Univ. Coll. ; Margaret G. P. Reed, King's Coll. ; H. G. St. M. Rees, Cardiff ; R. P. Ross, King's Coll. ; D. W. Seth-Smith, St. George's ; W. D. Sheldrake, Guy's ; Nancie A. Simmons, Charing Cross ; Beryl M. Stevens, Royal Free and St. Mary's ; R. D. Summers, London ; E. M. Town-Jones, Leeds ; Mary M. Tulloch, Charing Cross ; Aimee A. L. Vaillant, Charing Cross and Liverpool ; H. D. Weatherhead, St. Thomas's ; Gwendolen I. Wilkins, Royal Free ; Beatrice A. Wilkinson, King's Coll. ; Jane C. Williams, St. Mary's ; J. E. B. Williams, Univ. Coll. ; J. H. Williams, Cardiff ; and Eileen C. Wise, King's Coll.

Saint, London ; W. E. Savage, Manchester ; J. W. Schabort, Guy's ; G. Schewel, Hamburg and Westminster ; R. Schofield, Guy's ; Helen D. S. C. Scott, Charing Cross ; Evelyn I. M. Sheppard and H. L. Shimmin, Manchester ; C. W. Simpson, London ; Beatrice G. Smith, Univ. Coll. ; G. H. A. Soysa, Ceylon ; W. E. Snell, Univ. Coll. ; Dorothy E. Stewart, Royal Free ; C. N. Suter, St. Mary's ; A. G. S. Tabb, Charing Cross ; J. W. de W. G. Thornton, King's Coll. ; G. O. Tippett ; St. Thomas's ; H. A. Tracey, St. Bart.'s ; S. D. H. D. Wallis, Guy's ; N. Wassif, Charing Cross ; Edith M. Webb and Gwendolen I. Wilkins, Royal Free ; D. A. J. Williams, G. P. Williams, and J. H. Williams, Cardiff ; L. S. Williams, Guy's ; and Joan Worsfold, Royal Free.

The King has granted to Dr. James Ferguson Lees, C.B.E., lately Director-General of Public Health, Ministry of the Interior, authority to wear the decoration of the Order of Ismail (Insignia of the Second Class) conferred upon him by the King of Egypt, and granted to Dr. Robert Stewart Miller, Director of the Egyptian Hospital for the Insane at El Khanka, authority to wear the Insignia of the Fourth Class of the Order of the Nile, conferred upon him by the King of Egypt.

Royal College of Surgeons of England.—At an ordinary meeting of the Council of the Royal College of Surgeons on Nov. 12th, Sir John Bland-Sutton, President, in the chair, Mr. James Sherren was elected a member of the Committee of Management of the Examining Board in England. The President reported that at a meeting of the Executive Committee of the Streatfeild Research Fund on Oct. 7th Mr. Norman L. Capener, F.R.C.S., was appointed the third Streatfeild Scholar, the subject of his research being the Comparative Anatomy and Function of the Prostate Gland. A letter was read from Mr. Hugh Lett, resigning his membership of the Court of Examiners. The President reported that Mr. C. H. Fagge's term of office on the Court of Examiners would expire on Dec. 9th, and that the vacancy thus occasioned, together with that occasioned by the resignation of Mr. Lett, would be filled up at the ordinary Council on Dec. 10th. Diplomas of Member were conferred upon 204 candidates, whose names were given in The Lancet of Nov. 7th (p. 996).

Close of Consumptive Colony Hospital.—The Cumberland County Council have decided to close the Englethwaite Industrial Colony for the After-care of Consumptives, which last year cost the council £6800.

Society of Medical Officers of Health.—A meeting of the Fever Hospitals Medical Service Group will be held at the Society's House on Nov. 27th, at 3 P.M., when a paper on the Dick Test by Dr. R. A. O'Brien and Dr. C. C. Okell will be read.

King's College Hospital.—The annual report of King's College Hospital, which has just been issued, states that as the result of the recent special appeal, the outstanding liabilities, which were £36,000 at the beginning of the year, have been reduced to less than £15,000. Forty additional beds have been maintained in occupation.

Royal Sanitary Institute.—A sessional meeting of the Institute will be held on Friday, Nov. 27th, at 8 P.M., and on Saturday, Nov. 28th, at 10 A.M., in the Town Hall, Plymouth, when discussions will take place on the Disinfection of Ships, to be opened by Dr. G. A. Borthwick, port medical officer, and Some Points in Public Health Propaganda, to be opened by Dr. A. T. Nankivell, medical officer of health. The chair will be taken at 8 P.M. on Friday by Dr. W. J. Howarth. Those proposing to attend should notify the hon. local secretary, Dr. Nankivell, Plymouth, not later than Nov. 21st.

Messrs. Heffer and Sons, Cambridge, announce that they have in the press a volume by Dr. G. W. Nicholson entitled "The Nature of Tumour Formation: the Erasmus Wilson Lectures, 1925." The object of the lectures is to correlate knowledge of the cellular changes which result in tumour formation with the established facts of biology and physiology. The Oxford Medical Publications, London, are publishing a book by Mr. G. R. Girdlestone, B.M., F.R.C.S., on "The Diagnosis and Treatment of Tuberculosis of the Hip," which is an attempt to show how the objective of "a permanently safe and useful limb" may be reached by the safest and most direct route.

Belfast Maternity Home.—The Duchess of Abercorn last week paid a visit of inspection to the Belfast Maternity Home. In a speech she expressed her amazement that there are only 26 maternity beds to serve the whole Province of Ulster. Dr. R. W. Livingstone, Vice-Chancellor of Queen's University, stated that the conditions in which lectures are given to students at the Maternity Hospital were deplorable, and that the students were gravely handicapped in this branch of their training. He considered that the hospital was worthy neither of Belfast nor its staff, but Prof. J. A. Lindsay, the chairman of the Board of Governors, expressed the opinion that before a remedy was possible there would need to be better public recognition of the work of the hospital.

Crippled Children in Wales.—A meeting of representatives of county and local authorities in North Wales was held at Wrexham on Nov. 6th. The gathering was large and representative, being attended, amongst others, by Dr. D. Llewellyn Williams, chief medical officer of health for Wales, and Mr. Howell James, secretary of the Welsh Department of the Ministry of Health, presided. Sir John Lynn-Thomas urged the need for early treatment of the crippled child by persons specially trained to undertake it, and expressed the hope that provision would be made in the Prince of Wales Hospital, Cardiff, for the training of surgeons in orthopædic surgery. It was decided to form a Welsh branch of the Central Council for the Care of Cripples.

A Pioneer of Open-air Treatment.—A complimentary dinner was given at Shrewsbury on Nov. 7th to Miss Agnes Hunt, the founder of the Baschurch Surgical Home, which has now developed into the Shropshire Orthopædic Hospital. Among those present were Mr. W. C. Bridgeman, First Lord of the Admiralty, presiding, and many distinguished surgeons. Sir Robert Jones said Miss Hunt's methods, once described as visionary, were being imitated all over the world, not only in open-air treatment, but also in the establishment of after-care centres. Sir William Wheeler described Miss Hunt as the Florence Nightingale of the crippled children's world—"her lamp was the sun." At Baschurch, in 1900, half a dozen children were accommodated in an improvised shed in a garden, and now the institution, which took over the old war hospital at Park Hall, Oswestry, in 1920, accommodated some 340 patients from all parts of the country. Lord Kenyon presented Miss Hunt with a cheque for 1000 guineas and an illuminated album. There were over 500 subscribers to the testimonial—a gift of gratitude for 25 years' service for humanity whereby many thousands, apparently doomed to cripplehood, had been restored to strength and vigour.

Manchester: North-Western Tuberculosis Society.—A meeting of this society will be held on Nov. 26th at the Tuberculosis Offices, Joddrell-street, Deansgate, Manchester, when Dr. G. E. Loveday will read a paper on Vaccine-therapy with Special Reference to Tuberculosis.

Irish Medical Schools and Graduates' Association.—The autumn dinner of this Association will take place at Pagani's Restaurant, Great Portland-street, London, W., on Wednesday, Nov. 25th, at 7.30. Tickets may be obtained from Dr. J. F. Peart, 5, Harley-street, W. 1. The guest of the evening will be the Right Hon. Charles Andrew O'Connor, P.C.

French Medical Cruises, 1926.—The Compagnie des Messageries Maritimes have again organised two special cruises to the Mediterranean for members of the medical profession, to leave Marseilles on March 9th and April 21st, 1926, respectively, each tour occupying 30 days. Full particulars of these special cruises, as well as of other tours, can be obtained at the London offices of the company, 72–75, Fenchurch-street, E.C. 3, and 62, Pall Mall, S.W. 1.

Portmadoc Hospital.—This war memorial, established six years ago, has proved so useful that it has been decided to add new buildings. A site has been presented free by Dr. Richard Griffith, J.P., of Portmadoc. Donations of £200 have been received from Mr. J. E. Greaves, Lord-Lieutenant of Carnarvonshire, and £100 each from Mr. R. M. Greaves and Mrs. Charles Breese.

Bristol Hospitals Contributory Scheme.—Last year the total deficit on the working of the six Bristol hospitals was approximately £30,000. It has therefore been decided to establish a contributory scheme, and it is hoped to make arrangements with the participating institutions whereby persons with incomes exceeding £300 may, on payment in advance of £1 per annum, join a central association and receive the same benefits as the ordinary contributor.

Hospitals and Motoring Accidents.—At the anniversary meeting of governors of Nottingham General Hospital, Mr. James Forman, the President, pointed out that motor-car accidents represented 25 per cent. of the total casualty cases. He added that if there were as many admissions of victims of motor accidents in proportion during the next 12 months as there have been during the last eight, 2200 bed days would be occupied by them, and that there would be 190 patients in this category.

Royal Northern Hospital, London.—In aid of the hospital a fancy dress ball was held in the Royal Albert Hall on Nov. 12th. The date originally fixed was Armistice night, Nov. 11th, but this was subsequently changed to the following night. The ball, which was under the chairmanship of the Duchess of Sutherland, was a brilliant spectacle, the chief guest being H.R.H. the Prince of Wales. The extent to which the hospital benefited financially from this function will be announced later.

Royal Medical Benevolent Fund.—The treasurer (Sir Charters Symonds, 11, Chandos-street, W. 1) appeals for £350 to enable the committee to distribute to the annuitants and some of the most necessitous grantees a Christmas gift of 25s. Last year the remnant of the Dinner Fund (raised in 1913) was used for this purpose, and though subscriptions are coming in satisfactorily, the exhaustion of this "nest-egg" makes it difficult to meet this extra expenditure.

Dublin: National Maternity Hospital.—At the annual meeting of the National Maternity Hospital held last week it was reported that 871 patients had been admitted to the maternity wards during the year, and 402 to the gynæcological wards. In addition, 710 patients were attended at their own homes. It has been found impossible for the hospital to carry on its work without extension, and a site for extension has been obtained by the purchase of several adjoining houses. A sum of at least £10,000 will be necessary, however, before building can be undertaken. An appeal is now made for this sum.

Plymouth Medical Society.—At a recent meeting of this society the following officers were elected for the session 1925–26:—President, Mr. Gerald Robinson; vice-presidents, Mr. C. L. Lander and Dr. Colin Lindsey; hon. treasurer, Mr. J. Elliott Square; hon. librarian, Mr. H. Guy Ludolf; hon. secretaries, Mr. Cecil B. F. Tivy and Mr. James Riddel. Members of Council: Dr. R. J. Percy Thomas, Mr. H. F. Vellacott, Dr. T. M. Jamieson, Dr. A. Bertram Soltau, Dr. Eric Wordley, and Dr. R. H. Wagner. The library and rooms of the society are at Beaumont House, Plymouth.

Dr. John Divine, J.P., barrister-at-law, has been appointed coroner for Hull.

HOSPITAL OF ST. JOHN AND ST. ELIZABETH.—The new operating theatre, isolation ward, and X ray department at the Hospital of St. John and St. Elizabeth, Grove End-road, were formally opened last month by Cardinal Bourne. The theatre wing contains the operating theatre, a nurses' room, a large anæsthetic room (which is also used for minor operations), a wash-up room, a surgeons' disrobing room, a surgeons' dressing room with shower bath attached, and a store room; all the rooms lead off from a broad central hall. One of the features of the operating theatre is the apparatus for hot and cold sterile water and saline solution, which is fixed in the sterilising room and has pipes carried through the wall into the theatre. The theatre, one of the most up to date in England, has been built and equipped through the generosity of Mrs. H. G. Tetley, in memory of her late husband, Henry Greenwood Tetley. The architect is Mr. Keith Young, and the total cost of building and equipping was about £10,000. Mrs. Tetley has also endowed two private rooms in the hospital so that the board of management are able to receive, at an inclusive fee of £2 10*s.* weekly, patients whose circumstances do not admit their paying ordinary fees charged for private rooms. The isolation ward was erected through the generosity of Miss Winifred Berthe de La Chere. The X ray department, which was recently built by subscriptions collected by the chairman, Sir Charles Russell, is fitted with the latest appliances, and has photographic, treatment, and developing rooms. At the opening ceremony Mrs. Tetley and Miss de La Chere were presented with inscribed keys, and a reception was held in the hospital afterwards. Amongst those present were Viscount Fitzalan of Derwent (president of the hospital), Adele, Countess Cadogan, and the members of the board and honorary staff.

Parliamentary Intelligence.

HOUSE OF COMMONS.

MONDAY, NOV. 16TH.

PARLIAMENT reassembled after the summer recess.

Medical Enlistment for the Services.

Colonel DAY asked the Secretary of State for War whether any agreement had yet been reached with the British Medical Association in regard to their action affecting the enlistment of medical men into the Royal Army Medical Corps.—Sir L. WORTHINGTON EVANS replied: The pay and conditions of service of medical officers in the Navy, Army, and Air Force are being examined by an Inter-Departmental Committee appointed by the Government. The Committee has authority to take evidence from outside the Government service, and will, I understand, obtain the views of the British Medical Association on the subject.

Penal Reform.

Colonel DAY asked the Home Secretary whether the International Prison Commission, held in London during August, made any recommendation as to penal reform; and, if so, what recommendations were likely to be carried into effect.—Sir W. JOYNSON-HICKS replied: The proceedings of the Congress and the resulting resolutions will, it is hoped, be published shortly by the Secretary-General, Prof. Dr. Simon van der Aa, K.B.E., of Holland, when they will receive my careful consideration.

Progress in Housing.

Captain BOWYER asked the Minister of Health how many houses had been sanctioned, were being built, and had been completed under the Housing Acts of 1923 and of 1924 respectively.—Sir KINGSLEY WOOD (Parliamentary Secretary to the Ministry of Health) replied: On Nov. 1st the position under the Housing Acts of 1923 and 1924 was as follows:—

	Act of 1923.	Act of 1924.
No. of houses completed ..	116,811	15,122
No. of houses under construction	42,601	30,956
No. of houses definitely arranged for but not started	29,840	24,046
No. of houses authorised but not definitely arranged for ..	49,036	20,202
Totals (No. of houses authorised)	238,288	90,326

TUESDAY, NOV. 17TH.

Use of Insulin in Scotland.

The House considered the Public Health (Scotland) Amendment Bill on report. This measure authorises local authorities under the Scottish Public Health Act of 1897 to make arrangements for providing medicines and treatment to persons suffering from diabetes.

Dr. SHIELS moved, at the end of Clause I., which is the operative clause, an amendment providing that the Scottish Board of Health should require the local authority to arrange that any medicine used for the treatment of persons suffering from diabetes and who, in the opinion of the local authority, required assistance in obtaining such medicines and treatment, should be dispensed by a registered pharmacist, or by a registered medical officer or practitioner. He said insulin ought to be distributed under medical supervision. That precaution, he said, was already taken by the Poor-law authorities and under the National Health Insurance Acts. He did not see why the poor people who were to receive the insulin under this Bill should not have the same definite safeguards as others. Insulin was a very dangerous drug and unless it was distributed with care the results might be very serious.

Sir J. GILMOUR (Secretary for Scotland) said he was unable to accept the amendment. They all wished to see that the greatest safeguards were observed in the use of this drug. It was manufactured in bulk and sold in closed capsules. It was prescribed by a doctor, and at a certain stage of the treatment it might under careful medical directions be administered by the patient. So far as its purity was concerned it did not matter whether it was handed by the local chemist over the counter or dispensed by the local authority at their clinic. It could not be said that the risk of its being mishandled was any greater under the Bill than in the way proposed by the amendment. They were desirous that the Scottish Board of Health, working through the local authorities, should be able to dispense insulin at a price which would bear a fair comparison with that at which it could be obtained from a chemist's shop. The chemist would, of course, have to make a certain profit.

Sir A. SINCLAIR asked if there was any risk of deterioration in capsules and had not chemists previously been able to detect this fact and had they not rejected some of the supplies?

Sir J. GILMOUR said deterioration of the drug could not be detected by the local chemist.

Mr. WESTWOOD asked for a guarantee that only those persons properly qualified under the Pharmacy Acts should be allowed to manufacture insulin.

Sir J. GILMOUR said that he appreciated very much the natural and proper desire of Members to see that every precaution was taken in regard to the manufacture of this drug. He could give a guarantee that it was manufactured directly under the supervision of the Medical Advisory Council. So far as the handling and manufacture were concerned that was done by properly qualified people. The Bill dealt not with the manufacture but the distribution of the drug, and that was done in glass capsules so that the drug was properly protected.

Dr. SHIELS's amendment was rejected without a division.

On the motion for the third reading of the Bill,

Mr. W. ADAMSON said that although the Labour Party supported the Bill, they regretted that it was limited in its scope. The measure should have been extended to other diseases so as to bring the administration of public health in Scotland into line with England. An effective remedy might be found for cancer at any moment. It would be a tragedy if the poor people of Scotland could not get such remedy because of its costly nature.

Sir J. GILMOUR said that he appreciated the support of the Opposition in regard to this Bill. The problem of cancer, about which they were all anxiously waiting for a solution, was of such magnitude and so important that, in their judgment, it should be dealt with when it arose. No one could visualise either what the nature of the solution or the cost might be. In those circumstances they felt very strongly that if and when that solution was found there could be no reasonable doubt in the minds of anyone that Parliament would deal with it adequately and properly.

The Bill was read a third time, and passed.

Appointments.

COYTE, RALPH, M.B., B.S. Lond., F.R.C.S. Eng., has been appointed Assistant Surgeon to the Queen's Hospital for Children, Hackney-road, E.

GALLOWAY, R. L., M.B., F.R.C.S. Edin., Assistant Surgeon, North Middlesex Hospital, Edmonton.

HUTT, C. W., M.D. Camb., D.P.H. Oxf., Lecturer in Hygiene and Public Health, Charing Cross Hospital Medical School.

LINDEBERG, E. W., M.B., Ch.B. Glasg., Certifying Surgeon under the Factory and Workshop Acts for the Friockheim District of the County of Forfar.

PUGMIRE, GERTRUDE E., M.R.C.S., L.R.C.P. Lond., Surgeon, North Dispensary, Vauxhall-road, Liverpool.

St. Thomas's Hospital: Tompson, B. E., M.B., B.Ch. Oxon., Thomson, G. W. R., M.R.C.S., L.R.C.P. Lond., Rees, W. E., M.B., B.S. Lond., de Jersey, G. W. S., M.R.C.S., L.R.C.P. Lond., Wrigley, A. J., M.B., B.S. Lond., Barrett, J. C., V.C., M.B., B.S. Lond., Crawford, D. P., M.R.C.S., L.R.C.P. Lond., Dobie, J. M., M.B., B.Ch. Cantab., Casualty Officers and Resident Anæsthetists; Archer, E. C., M.R.C.S., L.R.C.P. Lond., Sims, T. H., M.B., B.Ch. Cantab., Rea, R. H. T., M.B., B.Ch. Cantab., Alexander, R. D., M.B., B.Ch. Cantab., Resident House Physicians; Cooke, A. M., M.B., B.Ch. Oxon., Resident House Physician for Children; Marks, D. P., M.B., B.Ch. Cantab., Boggon, R.H., M.R.C.S., L.R.C.P. Lond., Robinson, A. B., M.R.C.S., L.R.C.P. Lond., Battson, A. A., M.B., B.S. Lond., Resident House Surgeons; Wiener, R. A. K., M.R.C.S., L.R.C.P. Lond., Resident Orthopædic House Surgeon; Nicholson, H. W., B.A. Cantab., M.R.C.S., L.R.C.P. Lond., Resident House Surgeon (Ear); Rees, D. I., M.R.C.S., L.R.C.P. Lond., Resident House Surgeon (Throat); Robinson, J. J. R., M.B., B.S. Lond., Senior Obstetric House Physician; Heath, W. E., M.R.C.S., L.R.C.P. Lond., Junior Obstetric House Physician; Saunders, K. G. W., M.R.C.S., L.R.C.P. Lond., Senior Ophthalmic House Surgeon; Coverdale, H. V., M.B., B.Ch. Vacancies.

For further information refer to the advertisement columns.

Birmingham City Education Committee.—Asst. Sch. M.O. £600.

Birmingham, Selly Oak Hospital.—Res. Jun. Asst. M.O. £300.

Bradford Royal Eye and Ear Hospital.—Res. H.S. £120.

Bristol General Hospital.—Hon. Clin. Assts.

Cambridge, Addenbrooke's Hospital.—H.S. £130.

Cambridge, Mental Hospital.—Med. Supt. £800.

Cancer Hospital, Fulham-road, S.W.—Surg. Reg.

Cardiff City Mental Hospital, Whitchurch, near Cardiff.—Locum Tenens. 7½ guineas weekly.

Cardiff, King Edward VII. Welsh National Memorial Association.—Asst. Tub. O. £600.

Cardiff, Welsh National School of Medicine.—Lecturer in Pathology and Bacteriology. £750.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Res. H.S. £75.

Chelsea Hospital for Women, Arthur-street, S.W.—Jun. H.S. At rate of £100. Also Dental S.

Corporation of London Public Health Department.—Sanitary Inspector. £238 15*s.* 6*d.*

East London Hospital for Children and Dispensary for Women, Shadwell, E.—Asst. P. £50.

General Lying-in Hospital, York-road, Lambeth, S.E.—Res. M.O. At rate of £100.

Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each at rate of £50.

Hove Hospital, Sackville-road.—Res. M.O. £175.

Iraq Health Department.—Two M.O.'s. Rs.1200.

Italian Hospital, Queen-square, W.C.—Hon. Radiographer.

Liverpool, Hospital for Consumption and Diseases of Chest, Mount Pleasant.—Asst. M.O. and Pathologist. £150.

London Royal Free Hospital, School of Medicine for Women, 8, Hunter-street, W.C.—Sen. Second and Third Assts. for Obstetrical and Gynæcological Unit. £350 to £500. Also Res. Asst. Pathologist. £125.

Maidstone, West Kent General Hospital.—H.S. £220.

Manchester, Ancoats Hospital.—H.S. At rate of £100.

Manchester City Education Committee.—Asst. Sch. M.O. £600.

Manchester, Northern Hospital for Women and Children.—Sen. H.S. and Jun. H.S. £130 and £100 respectively.

Margate, Royal Sea Bathing Hospital.—H.S. At rate of £200.

Metropolitan Asylums Board.—Appointments in Tuberculosis Service. Sen. Asst. M.O.'s. £650. Jun. Asst. M.O.'s. £500.

Metropolitan Hospital, Kingsland-road, E.—Pathologist.

Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Sen. Res. M.O. and Jun. Res. M.O. £140 and £100 respectively.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Two Jun. Non. Res. H.S.'s. At rate of £100.

Northamptonshire County Council.—M.O.H. and Sch. M.O. £1100.

Prince of Wales's General Hospital, Tottenham, N.—Clin. Assts.

Prison Medical Service.—M.O. £495.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—H.P. At rate of £100.

Rochester, St. Bartholomew's Hospital.—Res. Surg. O. At rate of £250.

Royal Northern Hospital, Holloway, N.—Clin. Assts.

St. George's Hospital, S.W.—S. and Asst. S.

Salford Royal Hospital.—Res. Surg. O. £200.

Sheffield, Jessop Hospital for Women.—Asst. H.S. At rate of £100.

Singapore, College of Medicine.—Prof. of Biochemistry and Prof. of Biology. Each $850–$1000.

South Shields County Borough.—Ven. Dis. M.O. £750.

University College Hospital, Gower-street, W.C.—Med. Reg. £150. Also Hon. Dental S.

West Middlesex Hospital, Isleworth.—Asst. Med. Supt. £250.

Willesden General Hospital, Harlesden-road, N.W.—Hon. P.

York County Hospital.—H.P. £150.

The Chief Inspector of Factories, Home Office, London, S.W., announces a vacant appointment for a Certifying Factory Surgeon at Peterhead, Aberdeenshire.

Births, Marriages, and Deaths.

BIRTHS.

Aikman.—On Nov. 12th, at Westwood, Beaconsfield, the wife of Kenneth Blackie Aikman, M.D., of a daughter.

Cocking.—On Nov. 15th, at Strada Mezzodi, Valetta, Malta, the wife of Surgeon-Lieutenant-Commander A. Wilkinson Cocking, R.N., of a son.

Whitfield.—On Oct. 16th, at Trimulgherry, India, the wife of Captain C. A. Whitfield, R.A.M.C., of a daughter.

MARRIAGES.

Thomas—Last.—On Nov. 3rd, at St. Mary's, Bryanston-square, John Oscar Thomas, *M.C.*, M.D., M.R.C.P., to Dorothy Mary, daughter of Mr. and Mrs. Last, of Roselands, Clacton-on-Sea.

DEATHS.

Bardsley.—On Nov. 12th, Percy Crofts Bardsley, M.B., B.C. Camb., aged 59.

Blundell.—On Nov. 10th, at Holcombe, House, West Worthing, Hight Blundell, M.D., aged 61 years.

Gervis.—On Nov. 11th, at Belsize-park, N.W., Arthur Frederick Gervis, M.R.C.S., L.R.C.P. Lond.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Medical Diary.

Information to be included in this column should reach u in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Monday, Nov. 23rd.

ODONTOLOGY: at 8 P.M.
Casual Communication:
Mr. G. B. Pritchard: A Case of Exposure of the Pulp of Uncertain Origin.
Paper:
Mr. Harold G. Watkin: The Evolution of Radiography.

Tuesday, Nov. 24th.

Library: The Library will be open until 10 P.M.

MEDICINE: at 5.30 P.M.
Discussion on
The Clinical Aspects, Treatment, and Prognosis of Nephritis.
To be opened by Prof. Hugh MacLean.

Wednesday, Nov. 25th.

COMPARATIVE MEDICINE: at 5 P.M.
Paper:
Dr. Carey F. Coombs, Dr. Hadfield, and Mr. G. E. Henson: A Note on the Endocarditis of Swine Erysipelas and its Relation to Endocardial Lesions in Man.

Thursday, Nov. 26th.

BALNEOLOGY AND CLIMATOLOGY: at 5 P.M.
Presidential Address:
Dr. Llewellyn J. Llewellyn on Diathesis.

UROLOGY: at 8.30 P.M.
Clinical and Pathological Evening.

Friday, Nov. 27th.

Library: The Library will be open until 10 P.M.

BALNEOLOGY AND CLIMATOLOGY: at 10 A.M.
Joint Meeting with the International Society of Medical Hydrology to discuss The Treatment of Rheumatism in Industry.
The President of the International Society of Medical Hydrology (Dr. Gustave Monod, of Vichy) will occupy the chair, and the following are expected to take part in the discussion:
Sir George Newman, K.C.B., Chief Medical Officer to the British Ministry of Health; Dr. Van Breemen (Holland); Dr. Kerr Pringle (Harrogate); Dr. Otto May (London); Dr. Buckley (Buxton); Dr. Jansen (Denmark); Dr. Louis Blanc (France); Dr. Schmidt (Czechoslovakia); Dr. L. J. Llewellyn (London); Dr. M. B. Ray (London); Dr. Fortescue Fox (London); and others.

STUDY OF DISEASE IN CHILDREN: at 8.30 P.M.
Discussion on
The Diagnosis and Treatment of Splenic Enlargements in Children.
To be opened by Sir Humphry Rolleston, and continued by Dr. G. A. Sutherland, Mr. Arthur Edmunds, Dr. L. G. Parsons (Birmingham), and Dr. Hugh Thursfield.

EPIDEMIOLOGY AND STATE MEDICINE: at 8 P.M.
Paper:
Dr. A. K. Chalmers: National Death-rates in Relation to National Differences in Housing.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
MONDAY, Nov. 23rd.—8 P.M., Clinical Evening: Exhibition of Cases and Skiagrams.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
MONDAY, Nov. 23rd, to SATURDAY, Nov. 28th.—Fellowship of Medicine lecture, Medical Society, 11, Chandos-street, W. Mon., 5.30 P.M., Mr. G. R. Girdlestone: Tuberculosis of the Spine.—LONDON LOCK HOSPITAL, Dean-street, W. Instruction daily in the Out-Patient Department and lectures.—LONDON TEMPERANCE HOSPITAL, Hampstead-road, N.W. General Practitioners' Course, 4.30 to 6 P.M.—ROYAL WATERLOO HOSPITAL, Waterloo-road, S.E. Special Course in Medicine, Surgery, and Gynæcology. Lectures, demonstrations will be given in the Out-patient Department and Wards.—WEST END HOSPITAL FOR NERVOUS DISEASES, Welbeck-street, W. Lecture-demonstrations illustrated by cases, daily at 5 P.M.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.
POST-GRADUATE COURSE: OCTOBER-NOVEMBER, 1925.
CLINICAL LECTURES AND DEMONSTRATIONS.
MONDAY, Nov. 23rd.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Alterations in the Visual Fields: Mr. Williamson-Noble.
TUESDAY, Nov. 24th.—2 P.M., Out-patient Clinic: Dr. Walshe. 3.30 P.M., Neurosyphilis: Dr. Hinds Howell.
THURSDAY, Nov. 26th.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Methods of Testing the Eighth Nerve (in the Out-patient Department): Mr. Just.
FRIDAY, Nov. 27th.—2 P.M., Out-patient Clinic: Dr. Adie. 3.30 P.M., Cerebral Diplegia: Dr. Collier.
COURSE OF LECTURES AND DEMONSTRATIONS ON THE PATHOLOGY OF THE NERVOUS SYSTEM.
THURSDAY, Nov. 26th.—12 noon, Syphilis of Nervous System: Dr. J. G. Greenfield.
COURSE OF LECTURES AND DEMONSTRATIONS ON THE ANATOMY AND PHYSIOLOGY OF THE NERVOUS SYSTEM.
MONDAY, Nov. 23rd.—12 noon, The Autonomic System, (*b*) The Growth of the Mind: Dr. J. L. Birley.
Dr. H. J. Macbride is giving a COURSE OF EIGHT CLINICAL DEMONSTRATIONS, chiefly on METHODS OF EXAMINATION OF THE NERVOUS SYSTEM, in the Wards at 10 A.M. on Tuesdays and Fridays.
Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M. or at such other times as may be announced.
J. G. GREENFIELD, Dean of Medical School.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
THURSDAY, Nov. 26th.—3 P.M., Mr. T. H. C. Benians: The Investigation of Obscure Febrile Conditions. 4.30 P.M., Dr. F. G. Crookshank: Colon Bacillus Septicæmia.
Daily: In-patient and Out-patient Clinics in General and Special Departments, Operations, &c.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.
FRIDAY, Nov. 27th.—4 P.M., Mr. Nicol Rankin: Ear Ache.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.
TUESDAY, Nov. 24th.—5 P.M., Dr. A. Whitfield: Diseases Due to Fungi (2).
THURSDAY.—5 P.M., Dr. A. M. H. Gray: Bacterial Affections.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.
TUESDAY, Nov. 24th.—4.15 P.M., Dr. T. H. Oliver: Functions of the Pituitary Gland.
FRIDAY.—4.15 P.M., Prof. J. Shaw Dunn: Recent Work on Renal Function.

JAMES MACKENZIE INSTITUTE FOR CLINICAL RESEARCH, ST. ANDREWS.
TUESDAY, Nov. 24th.—4 P.M., Dr. I. McKenzie: Insulin in the Treatment of Toxic Delirium.
THURSDAY.—5 P.M., Mr. Lane Roberts: Conditions Leading to Obstructed Labour.

ROYAL INSTITUTE OF PUBLIC HEALTH, 57, Russell-square, W.C.
WEDNESDAY, Nov. 25th.—4 P.M., Dr. W. M. Willoughby: Infection in Ships and the Prevention of Spread Therefrom.

CHADWICK PUBLIC LECTURES.
THURSDAY, Nov. 26th.—8 P.M. (in the Lecture Hall, Royal Institute of British Architects), 9, Conduit-street, W., Mr. A. Macmorran, K.C.: Sanitary Provisions of the New Public Health Act, 1925.

Notes, Comments, and Abstracts.

THE DEVELOPMENT OF SPEECH IN THE NORMAL CHILD.

IN an address to the Child Study Society, on Nov. 12th, Mr. Macleod Yearsley described the results of his study of the development of speech in his son. Too little attention has been given, he considers, to normal development, which is necessarily the basis of all attempts to build up speech in abnormal children. The literature of the subject, he states, is very meagre, and has received no very notable additions save the fourth chapter of Wylie's "Disorders of Speech" since the appearance of Preyer's "Mind of the Child" in 1890. After summarising previous observations Mr. Yearsley gave an account of his own.

The first methods of communication are laughing, crying, and grunting, with facial expression and gesticulation. These precede, and are concurrent with, the development of speech, towards which the first steps are automatic exercises of the speech organs such as babbling, crowing, mimic reading, and echolalia. Automatic unconscious babbling may be compared to kicking and movements of the arms, and begins very early. The sounds *a-a-ah*, *e-e-e* and *oo-eh* were present on the third day and *laa-laa* on the fourth. On the twenty-fourth a nasal consonantal sound *na-na* was noted, and by the seventieth day the following sounds were heard:—*Aah*, *aah-boo*, *aah-goo*; *boo*, *boo-ah*; *goo*, *goo-ah*, *gur-gur-rll*; *tloo*, *l-loo-oo*, *lloo-loo*; *maa*; *naa*; *ooh*, *o-ur*, *oo-mum*, *oo-laa*, and "something beginning with a D." Crowing occurred on the seventieth day, and mimic reading about the thirteenth month. The place of babbling is gradually usurped by echolalia—i.e., unintelligent parrot repetition of adult speech, and this is important as a preliminary exercise. There were distinct traces of echolalia as early as the seventy-sixth day, when the boy often repeated his own name without the least intelligent application. On the 182nd day this, and the imitation of other sounds, was well marked. The sound of a watch excited him to *tick-tick-tick*, and on the 364th day he made the same noise when shown the picture of a watch. Sounds repeated easily by echolalia may give difficulty when intelligent speech is developed later. Wylie states that "the first efforts of intelligent speech call into action the higher and more conscious functions of the cerebrum, which as yet have had little or no concern with the process of articulation. Everything goes to show that the higher centres can learn their own duties with regard to speech and train the lower centres to prompt and perfect obedience only after a period of persevering effort." The boy frequently repeated *Loo-ey* by echolalia, but later had difficulty with his *l's*, and called himself 'Ouis. The letter *y* was frequently substituted for *l* as in "yadies" and "yetters." Understanding of spoken words comes before speech. Preyer's child, however, did not develop an ability to discriminate words heard until the twelfth month. On the 117th day Louis could clearly recognise "bottle," "up," "daddy," and "mummy." On the 253rd day he associated "dad-dad" with his father and "Peter Pan" with a picture; ten days later he waved his hand and arm of his own volition on hearing "Ta-ta," and on the 290th day said "Nan-nan-nan" to his nurse. The 333rd day was noteworthy because he said "daddy" when his father entered; he remarked "bath" when the article arrived on the 362nd day, and at 1 year 27 days he correctly answered the time-honoured questions about the peculiar utterances of cows and dogs with the words "moo" and "bow-wow." Three days later, when he was told that his father was about to take a bath, he said "dad-dad ba-baa." At 1 year 35 days he noticed a dog on his own initiative and said "woo-woo," and at 1 year 96 days began to ask the names of things by pointing to them and saying "*Er?*" At 1 year 116 days he remarked, "Fire," on seeing a stove, and replied "Ba!" on being asked where he was going; and at 1 year 136 days he visited the Zoo and called the lions *woo-woos* (a name appropriate to dogs), referred to a bear as "Be'r" (he possessed a teddy-bear), and imitated the sea-lions!

Another phase in the normal development of intelligent speech is the invention of words. Preyer's boy said *Momm* at 10 weeks, and subsequently whenever he was hungry. Romanes records the case of twin boys who invented a language and could not be induced to speak anything else for several years; they understood each other perfectly. Usually the words are partly onomatopoeic. Louis invented only four, namely, *A-wah-wah*=a horse (1 year 168 days, changed 15 days later to *Ah-vah*); *Fuf-fuf*=a motor vehicle, *woo-woo*=a dog, and (1 year 300 days) *num-nums*=grapes, apparently derived from *neum-neum*, which was a sign of pleasure on eating. At 18 months Louis had a vocabulary of 36 words, to which he added 15 by 19 months. At 21 months he had about 200 words, and at 2 years he had over 400. The first question was asked at 2 years 1 month, when he picked up a tie and said "What is that?" He has never ceased to ask questions since. The first answer was at 1 year 6 months, when he replied "A bear," and at 2 years 2 months he said, "No, I haven't." The first personal pronoun was used at 1 year and 5 months, when he remarked, "*My* daddy," and he said, "I want Nannie" at 1 year 10 months. The first personal pronoun, suggesting a realisation of personality, has been in continuous use since then, and 11 days after its first employment he used the second in "Oo want to go tatas too?" Sentences began at about 1 year 9 months, with such remarks as "Mummy cut it," and "Slide—hair—mummy's —broken—mend it." At 1 year 8 months he said (appropriately), "Roof — high — man — door—key—hole," which was an early step in speech production as it consisted of nouns only. At 2 years 7 months, on looking at a picture, he said, "Look at all those boats. There's one with smoke coming out of it. There's one with sails on it. There's one with a flag on it." A month later he expressed causality by saying, "When you get a lot of 'buses and taxis it makes *traffic*." At 2 years 11 months he was heard to murmur to himself, "Old Mother Goose, when she wanted to wander, didn't ride in a taxi or a 'bus. Oh, no! but she rode on the back of a very fine gander." At the same age he told his first story—on somewhat conventional lines—and developed an interest in puns. He said for instance, "That's a Russian engine—rushin' along," and "Is Brighton bright?"

The first three years of life may perhaps be apportioned as follows, always remembering that there is a certain amount of overlapping. The first year is spent in methods of communication which are part animal and part primitive human. These methods serve as a scaffolding beneath which articulate speech is built up. The second year is devoted to acquiring and experimenting with a vocabulary, and the third is occupied in perfecting and correcting. These three stages seem to recapitulate in brief the development of speech in the human race. The first year represents the long night of animal and pithecoid ancestry; the second the period of pleiocene or eolithic man, and the third represents the period of astonishingly rapid development from pleistocene or palæolithic man to the period of history. The marked difficulty of pronouncing words intelligently which came glibly with echolalia has been mentioned. It may be tentatively suggested that babbling and echolalia represent the earlier stages of proto-speech which made its mark on the organism very deeply, and is therefore more easily reproduced automatically in the young. Comparison of the speed at which speech was acquired by Louis and other contemporaries with the children's progress recorded by Wylie and Preyer shows a relative (and not undesirable) precocity in the modern child. Perhaps this may be explained by the fact that nowadays parents take a greater personal interest in their children.

THE TECHNIQUE OF THE ARTIST.

ANY attempt to grasp the technique of another art is a pleasant relaxation from the sometimes wearisome practice of one's own. Few medical men have leisure to attend any of the many series of critical lectures delivered by Mr. Stewart Dick at the National Gallery. Many will be grateful for their issue, suitably modified, in the form of a little handbook entitled "Hours in the National Gallery" (London: Duckworth, pp. 144, 3*s.* 6*d.*), to which Sir Charles Holmes has contributed an introduction. The volume is of convenient pocket size, and will help visitors to this and other galleries to keener appreciation of those differences in period, school, and manner that any collection rich in classical pictures has to offer.

CUTANEOUS PROTEIN TESTS.

IN a handbook entitled "Biological Therapy," Messrs. Parke, Davis and Co. have recently described the means of testing susceptibility to various specific proteins. The original material is extracted with water or physiological saline, to which a small quantity of a non-irritating preservative has been added. After the addition of glycerine it is concentrated and mixed with boric acid powder in sufficient quantity to make a rather stiff paste. It is claimed that the necessary activity and stability are thus obtained, and a small portion of each paste to be tested can be applied to as many as 25 small scarified areas on the arm without discomfort. A control reaction is observed, and a positive result is indicated within 30 minutes by the development of a definite weal not less than half a centimetre in diameter. For no apparent reason a test may be positive to-day and negative to-morrow, so that failure to get a reaction does not necessarily mean an absence of supersensitiveness, though it is doubtless accepted as such by the majority of observers. On the other hand, a positive result is said to be of definite significance. The unfortunate feature of the test is that a definite result is seldom given by one particular protein, whilst all others remain quite inactive; more frequently there is found a general idiosyncrasy for allied proteins. Such things as pollen, hair, feathers and dandruff, which come into direct contact with the respiratory mucous membrane, are more likely to give a definitely positive reaction than proteins, like those in food, which in the course of nature are subjected to digestive ferments. It may be noted that experiments by J. C. Walker[1] suggested that the younger the patient when asthma appears the greater the chance of protein sensitiveness being the important, if not the sole, ætiological factor, and in old people such a cause is certainly very rare.

MITCHELL BANKS MEMORIAL LECTURE AT LIVERPOOL.

Sir John Bland-Sutton delivered the Mitchell Banks Memorial Lecture on Nov. 5th in the Surgery Theatre of the University to a large audience representative both of the undergraduates and the profession as a whole. The lecturer chose as his subject Surgical Technique, and developed his theme with a world-wide wealth of allusion which made it at the same time fascinating to hear and provocative of thought. In speaking of methods of suture he passed from the simple armamentarium of the tailor bird through the use of living Michel clips in the shape of ants' mandibles by primitive peoples, up to the 50 different methods of closing the abdomen collected on the continent for a recent thesis. He deplored the lack of a perfect suture material. Turning to the varied methods of dressing wounds, he reminded his audience that, within the memory of those still living, cow-dung had been used for the purpose in this country, as it still was in India, where the "sanctity of the cow gave an added virtue to the cataplasm." The gilder used gold-beater's skin, whereas the carpenter employed glue and shavings, and in spite of all nature generally won. This observation had led him to discard dressings altogether except in cases where discharges required to be absorbed. The lecture, illumined by many a quiet shaft of humour, and borne along throughout on a deep under-current of philosophy, was brought to a close by a noble tribute to Lord Lister and the wonderful edifice of aseptic surgery which had been raised upon his work. At night Sir John Bland-Sutton was the guest of honour at the biennial dinner of the Liverpool Medical Institution. There was a crowded gathering of members and their friends at the Exchange Hotel. An interesting point was raised by Dr. Adami, Vice-Chancellor of the University, in replying on behalf of the guests. He pointed out how, in spite of the tributes constantly paid to the scholarship of classical centres of learning, none of our universities had followed their example in setting training of body and mind side by side as the ancients did. Only 200 of our 1800 undergraduates took part in the university athletics, and he thought that as medical men we should press for the establishment of a spacious gymnasium where men and women alike could discipline the body in rhythmic exercise and true physical culture, as an integral part of university life. Mr. R. Craig Dun, the president, who was in the chair, spoke of the Medical Institution and the admirable part it played in the professional life of the city.

THE CULT OF BEAUTY.

"WITH beauty comes the birth of beneficent optimism, the joy of living, the daring of creative effort, the elation and nobility of the personality—in a word, happiness." Such is the creed of the author of this book,[2] and when all allowance has been made for enthusiasm Dr. Frumusan does manage to convey the conviction that beauty and health go hand in hand. He urges that only with a return to the cult of the aesthetic in regard to our bodies will come that race regeneration with which the French as a nation are beginning to concern themselves. This return is to be accomplished by giving physical culture almost as important a place as mental culture in all educational establishments, and, while we in this country are considered by the author largely to have solved the problem by our school games, he would go further and cut down all time spent in school to five hours, of which three hours shall be devoted to study and two to physical exercise. But it is not only with the rising generation that Dr. Frumusan is concerned: the present generation is condemned for its habits, its clothing, its feeding, its ignorance on elementary matters of washing and cleansing, and, above all, for its sedentary method of living. Movement, from the cradle to the grave, is the keynote of the book, and while the author is often over-enthusiastic, there is running through it such a strong touch of common sense that it should make an interesting appeal to those concerned with health and the prevention of avoidable disease.

Bradshaw Lecture

ON

THE MUSCULAR DYSTROPHIES, SYMPATHETIC SYSTEM, AND ENDOCRINE GLANDS.

Delivered before the Royal College of Physicians of London on Nov. 5th, 1925,

BY EDWIN BRAMWELL, M.D. EDIN., F.R.C.P.,
PHYSICIAN TO THE ROYAL INFIRMARY AND MONCRIEFF-ARNOTT PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY, EDINBURGH.

I PROPOSE to confine my remarks to the group commonly denoted as muscular dystrophy with special reference to the ætiology of these disorders. I shall submit to you evidence from various sources which appears, to me at least, to suggest that the muscular dystrophies may not be myopathies or primary diseases of muscle, as they are generally regarded at the present time, but that their symptomatology may perhaps be determined by disease of the sympathetic nervous system. I shall also refer to the question of a possible relationship between the muscular dystrophies and the endocrine glands. While I admit that the evidence which I shall adduce is suggestive rather than conclusive, for it is based to some extent on observations which require further corroboration, my remarks may prove of value should they serve to focus attention upon points calling for elucidation in the determination of this problem.

The observation, that in the majority of cases of muscular dystrophy the sternal portion of the pectoralis major wastes while the clavicular portion escapes, is well known to all clinicians. It has often occurred to me that this very striking fact must afford a clue to, or at any rate must be taken into consideration in any explanation which may be advanced to account for, the incidence of the muscular involvement in these disorders. I shall in the first instance approach the problem from this standpoint, but it may be well that I introduce my remarks with a brief and pertinent historical prelude with special reference to the ætiological considerations which it is my present purpose to discuss.

THE RECOGNITION OF THE MUSCULAR DYSTROPHIES.

Aran's communication,[1] published in 1850, was the means of directing general attention to the progressive muscular atrophies. Ten years later Luys (1860)[2] observed changes in the grey matter of the spinal cord in cases of the kind, and in 1874 Charcot expressed the opinion that the paralysis and wasting in cases of progressive muscular atrophy were due to a chronic degeneration of the anterior horn cells of the spinal cord. This view, which was for a time opposed by Friedreich and others, who regarded the cell changes in the spinal cord as secondary, before long met with general acceptance. Various clinical types of progressive muscular atrophy had, however, been previously differentiated in which no spinal cord changes had been observed. Thus Meryon (1852),[3] in a communication entitled a Granular and Fatty Degeneration of the Voluntary Muscles, described four cases of progressive muscular atrophy in brothers, in one of which, examined post mortem, the muscles presented the appearances referred to in the title of his paper, while no abnormality was found in the spinal cord. Then in 1861 Duchenne of Boulogne published his classical description[4] of pseudohypertrophic paralysis. Again in 1875 Leyden[5] reported certain cases of muscular atrophy, occurring in families, to which he applied the designation "hereditary type of progressive muscular atrophy." Gowers,[6] whose monograph upon pseudohypertrophic paralysis appeared in 1879, clearly recognised that "hypertrophy and atrophy may exist in different proportions, and there are cases which connect the two extremes—in some enlargement of many muscles, and in others wasting of all." Erb,[7] of Heidelberg, in 1883 described his juvenile type, and three years later (1885) Landouzy and Dejerine[8] a form, which differed merely from the juvenile type of Erb in that the facial musculature was involved, to which they applied the term "facio-scapulo-humeral." The recognition of the types last mentioned is of especial interest, since progressive muscular atrophy in the adult had previously been believed to be of myelopathic origin.

Erb[9] was chiefly responsible for placing our knowledge of these disorders upon a sure footing. Basing his conclusions upon a large series of cases which he had personally examined both clinically and pathologically, Erb laid it down that there are two kinds of progressive muscular atrophy, one in which there is a degeneration of the anterior horn cells to which the symptoms are to be directly attributed, and another in which no such changes are observed. To the latter group he applied the term muscular dystrophy. Further, he demonstrated that these two groups of cases differed not only in the distribution and nature of the atrophy, but also in the structural changes presented by the muscles. Again, he pointed out that the types described by Meryon, Leyden, Moebius, Duchenne, Landouzy and Dejerine, and himself were merely variations of the same disease.

THE PRIMARY MYOPATHIC VIEW A NEGATIVE CONCEPTION.

While the earlier writers agreed as to the absence of changes in the spinal cord, numerous cases of muscular dystrophy have since been reported in which a reduction in the number and size of the anterior horn cells has been observed. These changes have, however, been regarded as of secondary origin. Thus Gordon Holmes,[10] who in 1908 reported a case of pseudohypertrophic paralysis in which such changes were present, and reviewed the literature up to that date, writes :—

> "The histological changes in the ventral horns in my case were, it seemed to me, quite distinct from the degenerative cell changes I have found in any of the many spinal amyotrophies which I have examined, and the muscular affection exceeds them very much in both degree and extent . . . the most probable explanation of these cases is that the neural changes are secondary to the primary muscle disease."

Further, he adds :—

> "It appears to me very improbable that the myopathies have a neuropathic basis, indeed, I cannot see how this contention can be logically sustained. In the first place, there is no reason why the muscles of certain individuals should not possess a morbid tendency to regressive changes quite as well as parts of the nervous system, and, secondly, in the majority of cases which have been examined no histological evidence of nervous change to which the muscular atrophy could be secondary has been found."

The generally accepted view according to which the muscular dystrophies are of primary muscular origin is, however, a negative conception, for it is essentially based upon the negative findings in the nervous system. It is, indeed, interesting to note that Landouzy and Dejerine suggested in 1886[11] that although the nervous system has been found normal in muscular dystrophy, it may nevertheless be altered in a way we are unable to detect, an opinion which was also held by Vulpian. Again Erb wrote in 1890 :—

> "I cannot avoid the suspicion that after all the affection may be dependent upon the nervous system. It is tempting to suppose, as I formerly expressed it, that we have to do with a kind of tropho-neurosis having its origin in the trophic centres of the cord—a disturbance of the function of these centres which finds its expression in the very complicated muscle changes of the disease. A further rich experience, much thought expended upon the question, and particularly the above described anatomical findings (he refers to the changes in the muscles observed in poliomyelitis), have served to confirm me in my scruples."

New data have of late emerged which have a bearing on this problem, and I shall now direct your attention to certain apposite facts and discuss the conclusions which would appear to be legitimately derived from them.

Inferences from Comparative Anatomy.

The incidence of the muscular involvement in the common types of muscular dystrophy—the atrophic type without muscular enlargement, the pseudo-hypertrophic paralysis of Duchenne, the juvenile type of Erb, and the facio-scapulo-humeral type of Landouzy and Dejerine—is strikingly similar. (I do not include the distal type, since I am not satisfied that these cases are distinct from peroneal muscular atrophy. Again, I have omitted myatonia congenita, regarding which there is still considerable difference of opinion, as also myotonia atrophica, which I am inclined to think is a distinct disease.) Although great individual variations are met with, certain muscles are very commonly picked out, while others are as commonly spared. The question arises, Does comparative anatomy afford any explanation of the facts? A study of the earlier stages of the disease is, you will agree, more likely to prove informative than at a later date when the atrophy has become generalised. The case of a miner at present under my care provides a useful illustration for discussion, since the atrophy is very localised and complete, although its distribution is in some respects exceptional.

The patient, aged 46, is a particularly muscular man. He has suffered from no illness of a serious nature, nor, so far as he is aware, have any cases similar to his own occurred among his relatives. He states that, some ten years ago, he first noticed slight "stiffness" about the shoulders. The condition has, he thinks, become slowly more pronounced, but that it has not until recently given rise to any serious disability is evident from the fact that almost up to the time of his admission to hospital he was capable of doing a full day's work.

On examination a very localised but very complete bilateral atrophic paralysis is present. The muscles involved are the latissimus dorsi, the trapezius (including the upper third), the sternal portion of the pectoralis major, the serratus magnus, and the rhomboids, all of which are much wasted and absolutely powerless. The levatores anguli scapulæ are somewhat weak and wasted, especially on the right side. The brachioradialis is absent. All the muscles of the body apart from those mentioned are well developed and powerful, including the sternomastoid and the clavicular portion of the pectoralis major, the teres major, spinati, deltoid, and the muscles of the trunk and lower limbs. No fibrillary tremors are to be observed. There is no sensory loss and no alteration in the reflexes.

The atrophic paralysis in this case is limited, with the exception of the brachioradialis, to the extrinsic muscles of the shoulder-girdle. All these muscles are indeed completely paralysed excepting for the sternomastoids and the levator anguli scapulæ (the last-named muscle being somewhat weak and atrophic), and yet the patient suffers little inconvenience in consequence. The distribution of the atrophic paralysis if limited is, you will agree, characteristic of muscular dystrophy, although the fact that the levator anguli scapulæ and the upper third of the trapezius are affected is unusual, for these muscles are not, as a rule, involved until the later stages of the disease. Does comparative anatomy throw any light upon the localisation of the atrophic paralysis? Those of you who have read Sir Arthur Keith's fascinating Hunterian lectures[12] upon Posture: its Evolution and Disorders, will recall that he points out that in the pronograde animal the weight of the body is transferred to the upper limbs by a series of muscular slings or hammocks which are constituted by the extrinsic muscles of the shoulder-girdle, and that in the arboreal anthropoids, in which the arms and shoulders have to sustain the weight of the trunk, certain modifications take place in the musculature of this region. On the other hand, in man the trunk has to sustain the weight of the shoulders and arms, and "consequently we have here only to suppose a perfecting of a supporting reflex mechanism for the maintenance of the shoulders—a human character of late evolution." Now, is it not a striking fact that in the great majority of cases of muscular dystrophy it is the extrinsic muscles of the shoulder-girdle—the latissimus dorsi, the lower part of the pectoralis major and trapezius, the rhomboids, and the serratus magnus—which are prone to suffer; while, on the other hand, I think you will agree that the sternomastoid, as also the upper part of the trapezius and levator anguli scapulæ, the latter being muscles which constitute part of the sling system, but which have acquired new functions in relation to the supporting reflex mechanism necessitated by the erect posture, are in the earlier stages at any rate but seldom involved.

The escape of the clavicular portion of the pectoralis major calls for separate consideration. The pectoralis major is referred to by Dr. C. E. Beevor[13] as "one of the most interesting muscles of the body." As Wilfred Harris[14] has pointed out, the clavicular head below the gibbon is replaced by the anterior fibres of the deltoid. Indeed, Sir Arthur Keith indicates that the clavicular head of the pectoralis major is a new muscle—a late development in the process of evolution.

The absence of the brachioradialis in this case is of much interest. This muscle is, in my experience, very often absent in the muscular dystrophies. I have met with three additional cases in which it was absent, while all the other muscles of the forearm and upper arm were intact. The brachioradialis is really an upper arm muscle. W. Colin Mackenzie[15] points out that while in some animals, for example, the wombat, it is a muscle of great importance, in man it is "struggling hard to retain its place in the human economy." It would indeed appear in man to be a retrograde or regressive muscle with a comparatively unimportant function. And yet Sir Arthur Keith writes me it is a muscle which "is wonderfully constant—never absent."

These considerations would appear to suggest that it is the regressive or primitive muscles, as exemplified by the brachioradialis, which are especially predisposed in the muscular dystrophies, while, on the contrary, a muscle which is acquired late in the process of evolution—as is the case with the clavicular portion of the pectoralis major—and muscles which take on new functions in relation to the erect posture—as, for instance, the sternomastoid and upper part of the trapezius—escape.

Conclusions Derived from Embryological Observations.

The well-known observations of Babinski and Onanoff,[16] reported many years ago, are of much interest in relation to the problem under discussion. These observers found that the muscles of a five-months' fœtus varied greatly in their degree of development. Further, they noted that it is those muscles in which development is most advanced which are especially prone to suffer in the muscular dystrophies. In other words, their observations indicate that there is an intimate association between the degree of rapidity of the muscular development and the degree of predisposition to muscular dystrophy. Babinski and Onanoff employ figures with which to indicate the degree of development of the individual muscles, and tabulate their results as follows:—

Hand: muscles of thenar eminence, 2; muscles of hypothenar eminence, 2.

Forearm: brachioradialis, 5; extensors and pronators, 3; flexors of the fingers, 2.

Upper arm: biceps, 3; triceps, 3.

Shoulder, intrinsic muscles: deltoid, 4; infraspinatus, 3; subscapularis, 3. Extrinsic muscles: serratus magnus, 5; latissimus dorsi, 5; rhomboids, 5; adductor portion of trapezius, 5; clavicular portion of trapezius, 2.

Face: orbicularis palpebrarum, 5; masseter, 2; muscles of the auricle, 1.

Lower limbs: quadriceps, 5; calf muscle, 3; anterior tibial, 5.

It is interesting to compare these observations upon the development of the muscles in the fœtus with the incidence of the muscular involvement in the muscular dystrophies and with the observations on comparative anatomy to which I have just referred.

INCIDENCE OF MUSCULAR INVOLVEMENT REGARDED FROM THE STANDPOINT OF FUNCTION.

The problem of the incidence of muscular involvement may also be considered clinically from the point of view of function. Sir Charles Sherrington [17] has pointed out that while in various invertebrates individual muscles are specially differentiated for the execution of movements and the maintenance of posture, in the vertebrates, on the other hand, "the same muscle is used for the two purposes, though some muscles are predominantly concerned with one, some with the other function." Again, in the case of certain vertebrates, the rabbit, for instance, as Ranvier long ago demonstrated, some muscles—those which are obviously concerned more especially with active movement—are paler in colour than others which are obviously more especially concerned with the function of fixation. In man, however, there is no such difference in the naked-eye appearance of the individual muscles, nor, so far as I am aware, have two kinds of muscle-fibre been differentiated. Consequently, while further observation may serve to establish the presence of two kinds of fibres in the muscles of man, the possibility must be admitted, in the absence of evidence to the contrary, that the two functions—execution of movement and maintenance of posture—may be subserved by the same muscle-fibre.

The distribution of the muscular involvement in the muscular dystrophies suggests, I think, that muscles which are of special importance as fixators in relation to the maintenance of posture are predisposed, whereas muscles more especially concerned with active purposive movements of which we are more directly conscious are either spared or only suffer at a later date. We have already seen that the extrinsic muscles of the shoulder-girdle are commonly in great part involved, although the sternomastoid, upper part of the trapezius, and the levator anguli scapulæ as also the clavicular portion of the pectoralis major, which is, as I have mentioned, an intrinsic muscle, as frequently escape. Again, in the juvenile and facio-scapulo-humeral types the upper arm and thigh muscles are also affected. Further, when the muscles below the elbow and knee suffer, is not the weakness commonly most pronounced in the extensors of the wrist and the anterior tibial group, while the flexors of the fingers and the calf muscles, though the latter may be enlarged, remain comparatively powerful until a much later date? Dr. Beevor[18] laid it down that—

> "We have to differentiate in any movement between the muscles which take part directly in that movement and the muscles which are used to fix the joints which lie between the joint which is actively engaged and the fixed point or base on which the structure works."

The extensors of the wrist and the muscles of the upper arm play an important part as fixators in forcible grasping, while in running the anterior tibial muscles and the muscles of the thigh play a similar and equally prominent rôle. Now it is these muscles, which are especially concerned with fixation, which are at any rate first affected in the muscular dystrophies. On the other hand, the flexors of the fingers, the small muscles of the hand and the calf muscles, which are the prime movers in relation to the most important functions of grasping and running, tend to escape, as do the small muscles of the hand. Is it not the case, speaking generally, that as we pass from the periphery towards the trunk the muscles play a relatively more prominent part in relation to fixation as compared with conscious purposive movement? I would submit that muscles which are predominantly concerned with fixation are especially predisposed in the muscular dystrophies. This apparent relationship of the incidence of the atrophy to function suggests, does it not, a difference in nerve-supply?

DUAL INNERVATION OF SKELETAL MUSCLE.

It has long been known that the skeletal muscles are innervated by the somatic nerves which arise from the multipolar cells in the anterior horn of the spinal cord. Recent observations would, however, appear to indicate that the skeletal muscles also receive a sympathetic nerve-supply. Prof. J. T. Wilson,[19] who has summarised the evidence from the histological standpoint, concludes that—

> "It is difficult, if not impossible, to avoid the conclusion drawn by Boeke and supported by Agduhr and others from the results of what would appear to be crucial experiments, that these accessory fibres are sympathetic in origin and hypolemmal in their mode of termination. These relationships, if admitted, would seem to indicate a centrifugal conduction along these fibre paths of nerve impulses, presumably of motor and possibly of tonic contractile character."

The subsequent investigations of the late Prof. Irvine Hunter [20] upon this subject have, as you know, aroused widespread interest. While it is not my intention to discuss this question I may remind you that it was Kulchitsky's observation [21] "that the medullated and non-medullated fibres never terminate in the same muscle-fibre" which inspired Hunter's investigations. Hunter came to the conclusion from his histological and experimental observations that the differentiation of muscles into "movement" and "fixing muscles," which is so apparent in some invertebrates, is not lost in vertebrates, and that "the skeletal muscle of vertebrates consists of two sets of muscle-fibres disposed in groups each with its own specific innervation and consequently its own specific function." These two muscle systems of invertebrates are, he affirmed, represented as small muscle groups which mingle together to constitute the skeletal muscles of vertebrates. Further, Hunter's investigations led him to suggest that there are two kinds of muscle tone—first, "plastic" tone, which is responsible for the maintenance of any posture once it has been assumed, a function which he believes to be subserved by the sympathetic; and, second, "contractile" tone, which imposes posture on a limb as a result of shortening of appropriate muscles. These investigations and conclusions have been criticised by Walshe [22] who, in a brilliant review of Hunter's work, concludes that a sympathetic motor innervation of striated muscle has not yet been satisfactorily established, and that the experimental investigations undertaken to demonstrate the existence of two forms of tonic muscular activity, plastic and contractile, have not succeeded in doing so. It is, in Walshe's opinion, extremely doubtful if postural tone can be so divided into two separable components, and "consequently the question of a sympathetic innervation of a hypothetical 'plastic' component of postural tone cannot arise until the morphological problem is settled and until the existence of such a component has been demonstrated." Walshe's destructive criticism is of the greatest value, since it serves to indicate the possible fallacies and gaps in the chain of evidence, and indicates the necessity for caution in distinguishing between hypothesis and proved fact. At the same time, after carefully reading his review, I am still left with the impression that there is good reason for believing that the non-medullated fibres which pass to the skeletal muscles are probably sympathetic in origin and that they terminate in the muscle-fibres. In other words, as Langley, whom Walshe quotes, remarks, "the evidence is decidedly in favour of Boeke's views." Further, it is obvious that these fibres must have some function, and if they do terminate in the muscle-fibres, as the evidence would suggest, it seems probable that they are concerned with movement and very possibly with the maintenance of posture. The suggestion that the sympathetic supply to skeletal muscle has to do with muscle tone, the maintenance of posture and fixation has not been definitely proved; nevertheless, the evidence bearing on the point is, I think, very suggestive.

DEDUCTIONS FROM HISTOLOGICAL APPEARANCE OF MUSCLES.

I shall now very briefly direct your attention to the histological appearances of the muscles in the muscular dystrophies in so far as they appear to have a bearing upon the question at issue. Our knowledge of these appearances, which have been studied and described in detail by many observers, has been derived in part from the examination of portions of muscle excised during life and in part from post-mortem examination. The changes met with vary according to the stage of the disease and are characteristic, if not absolutely distinctive. Again, while they present certain common features, they vary in different muscles and even in different parts of the same muscle. In some muscles, and this would seem to be the earliest stage, the muscle-fibres are swollen and show a rounded contour with poor striation, an increase of nuclei, and little if any increase in the interstitial tissue. On the other hand, in other muscles many fibres of unusually small calibre are met with, together with a great increase of interstitial tissue, thickening of the wall of the blood-vessels, and narrowing of the lumen. The enlarged muscles of pseudohypertrophic paralysis may be found to consist chiefly of large fibres. Later both large and small fibres are found, together with a great interstitial deposit of fat. Eventually the fat is absorbed and the muscles diminish in bulk.

How are these various appearances to be explained? The possibility that the primary change consists in an increase of connective tissue with secondary alterations in the muscle may be dismissed, since in some of the muscles the fibres show pronounced pathological changes with little or no increase in connective tissue. Further, the whole trend of pathological thought of recent years has been to regard proliferation of interstitial tissue as a secondary compensatory process. We see this exemplified, for instance, in relation to certain diseases of the kidney, liver, and heart. Are the muscle changes primary? This is the view which is generally accepted at the present time. On the other hand, the increase of interstitial tissue is often very much greater than one would expect were its increase due to a secondary compensatory process. It is often, for instance, very much more pronounced than that which is met with in the muscular atrophies of spinal origin. This being so, is it not more probable that both the changes in the muscle and in the interstitial tissue are due to a common cause? I would remind you that Duchenne, in writing of pseudohypertrophic paralysis,[23] remarked:—

> "The causative irritation which produces the abundant muscular proliferation and the other alterations in the interstitial connective tissue of the muscles, appears to me to be the probable cause of their enfeeblement. But how is this alteration to be explained and at the same time the change in the connective tissue? This is a problem still awaiting solution."

The suggestion has been advanced that the thickening of the walls and narrowing of the lumen of the blood-vessels which are often to be seen in the connective tissue may be the determining cause. Buzzard and Greenfield,[24] for instance, referring to these changes in the blood-vessels, remark:—

> "It is thus possible that the disease is primarily one of the sympathetic system and that inadequacy of blood-supply to a muscular area may determine the changes in the muscle-fibres. But the bulk of opinion favours the hypothesis that the muscles themselves are primarily affected and that the interstitial and vascular changes are secondary."

The thickening of the blood-vessels is, however, only observed when there is a pronounced increase of interstitial tissue, consequently it would seem to be unlikely that the appearances in the muscles are due to a defective blood-supply. Possibly, however, we have here an explanation of the localised atrophy and "the cricket-ball appearance" which, although only occasionally met with, is so characteristic.

Is it not possible that if both the changes in the muscle-fibres and the increase of interstitial tissue are due to a common cause they may both be a direct consequence of disturbance of sympathetic innervation? Have we not a possible analogy in the tabetic arthropathies? Here we find trophic changes in bone, a tissue of low order. While in some arthropathies there is a great bony increase, in other instances the process is apparently atrophic from the first. We know little if anything of the changes in the muscles which follow sympathectomy. Hunter's observations [25] are suggestive in this connexion, for he has noted the presence of a number of small fibres, an observation which would appear to indicate that the sympathetic has a trophic influence on the muscle, and he also appears to have observed an increase of interstitial tissue greater than that which follows division of the somatic fibres. Thus he writes:—

> "In the case of sympathetic denervation which removes plastic tone, increase in fibrous tissue no doubt renders the muscle more efficient in maintaining a position imposed by active movement or by selective reflex activity. When contractile tone is removed by somatic denervation only a very slight increase of connective tissue occurs over a period of 60 days."

This sentence would certainly seem to suggest that Hunter observed a greater increase of connective tissue after sympathetic than after somatic denervation. Further experimental observations are, however, required with direct reference to this point. Lastly, I would remind you that Erb long ago pointed[26] out that in acute poliomyelitis similar morbid changes (hypertrophy, proliferation of nuclei, division of the fibres), both in the muscles and connective tissue had been noted by W. Muller, Dejerine and Huet, Joffroy and Achard, and Hitzig. But is it not the case that poliomyelitis is a disease in which changes referable to the sympathetic system—coldness and discoloration of the limbs, atrophic changes in the bones and contractures—are often pronounced? In chronic progressive muscular atrophy of spinal origin, in which the pathological changes are limited to the anterior cornual cells, no such changes are observed.

SYMPTOMATOLOGY APART FROM THE MUSCULAR ATROPHY.

Some of the phenomena observed in cases of muscular dystrophy cannot be accounted for on the assumption that these disorders are due to a primary disease confined to the muscles. The marbled appearance of the skin, which is not uncommonly seen in the muscular dystrophies, was such a striking feature in Meryon's cases that this observer was led to suggest a sympathetic origin for the disease. Contractures are often met with both in the early and later stages. They have been especially studied by Hahn [27] and others. Again, while contractures are not observed in the chronic progressive muscular atrophies of spinal origin, they constitute a feature of the clinical picture in many cases of acute poliomyelitis, a disease in which other manifestations pointing to disturbance of the sympathetic system are often present. Further, trophic changes in the bones have been described by Friedreich, Le Gendre,[28] Schlippe,[31] Dreyer,[32] Schultze,[30] Spiller,[29] Timme,[37] and others. Spiller remarks: "In a case reported by me the bones were undoubtedly involved, which seems to indicate that the disease may not be merely muscular." Schlippe, too, believes that the skeletal changes are brought about most probably by the same cause that produces the changes in the muscles. The thigh bone in one of Schultze's cases was only the thickness of one's middle finger, and the humerus was still thinner, the medullary cavity being very small. In the case of a boy of 15 with a muscular dystrophy of the pseudohypertrophic type at present under my care, the bones are almost as thin as in Schultze's case, though they are of normal length. Eulenberg[35] and Bregmann,[36] on the other hand, have reported cases of muscular dystrophy in which the bones were hypertrophied. Changes in the heart muscle have, I may remind you, been found by Bunting,[33] Potter,[34] Globus and others in pseudohypertrophic paralysis. Again, intellectual impairment, which is generally admitted to be not infrequent, led Duchenne at first to believe that he was dealing with a cerebral disease. Further, as I shall presently point out, pronounced disturbance of the endocrine glands is an occasional accompaniment, while it may be that slighter degrees of endocrine disturbance are not infrequent. These facts all suggest, do they not, that the atrophy of the muscles in the muscular dystrophies is to be regarded as merely the most prominent manifestation of a pathological process which is not confined to the muscles but is much more generalised.

HYPERTROPHY AND PSEUDOHYPERTROPHY.

Enlargement of muscles is a striking feature of some cases of muscular dystrophy. Very exceptionally, as in the case figured by Duchenne, most of the muscles are enlarged. As a rule, however, the enlargement is limited to certain muscles. It may be that the enlargement is sometimes a true compensatory hypertrophy as in two cases I have observed, in which there was great wasting of the quadriceps group, while the tensor fasciæ femoris was very large and powerful. The muscles in this case were not, however, examined histologically. In pseudohypertrophic paralysis enlargement of muscle is typically observed. But it is a mistake to suppose that the enlarged muscles are necessarily weak muscles. The increase in size may, as has been shown, be due, in the earlier stages at any rate, to an increase in size of the muscle-fibres, and there may be no increase of interstitial tissue and fat—i.e., no pseudohypertrophy. I have, for instance, under my care a boy of 11 with great enlargement of the calves and some contracture of the calf muscles, as a consequence of which he walks on his toes. The movement of plantar flexion of the feet in this case is very powerfully carried out against resistance; indeed, I am almost inclined to say that the power evinced suggests a true hypertrophy of the calf muscles; on the other hand, dorsiflexion of the feet is overcome with comparative ease, although there is no actual wasting of the anterior tibial group. The muscles of the upper extremity most often enlarged in pseudohypertrophic paralysis are the spinati, deltoid, triceps, and the extensors of the forearm; while the muscles of the lower limbs, in which enlargement is most often observed, are the gastrocnemii, glutei, quadriceps, and sartorius. Enlargement of the trunk muscles, the serrati, masseters, and tongue is occasionally observed. Very exceptionally are other muscles enlarged. Why is it that some muscles should show a tendency to enlarge, while others, if affected, invariably waste from the first, and why do certain muscles enlarge more often than others? It is, I think I may say, speaking generally, the bulky muscles which usually show enlargement. Is it possible—I put forward this suggestion with considerable diffidence—that these muscles are, on account of their bulk, of especial importance as glycogen storers, and that the enlargement is in some way associated with this function?

Why does pseudohypertrophy occur in some cases of muscular atrophy and not in others? This is not to be explained by the age factor, for although pseudohypertrophy is pre-eminently met with in the cases which occur in childhood, it is not observed in all children suffering from muscular dystrophy, and it is also met with in adults as, for example, in some cases of the juvenile type. Then, again, it is not an essential family trait, for a number of instances have been recorded (Erb, Gowers, Byrom Bramwell, and others) in which some members of a family have suffered from pseudohypertrophic paralysis and others from the same type of muscular dystrophy but without enlargement of the muscles. Obviously, under such circumstances individual predisposition must be the determining factor. A relationship between the muscular dystrophies and the endocrine system has recently been suggested, and I shall presently cite cases which appear to indicate a relationship between disturbance of pituitary function and pseudohypertrophic paralysis. I would suggest that the pseudohypertrophy may possibly be a superadded phenomenon so to speak, and that its occurrence may be determined by a tendency to hypopituitarism, the fat being absorbed at a later date in response to the economic demands of the tissues. Falta[38] refers to a case of hypophyseal dystrophy reported by Marinesco and Goldstein in which fat-permeation of the muscles was apparently found, and he states that this is also observed in primary genital adiposity and in castrated animals.

CAUSE OF THE PARALYSIS.

The sympathetic supply to skeletal muscle is part of an involuntary system, and if the muscular dystrophies are due to disease of the sympathetic, how are the loss of power and atrophy to be explained? If it is the case that the same muscle-fibre is innervated by both somatic and sympathetic nerve-fibrils, may it be that disease of the latter eventually interferes with the voluntary contractile function of the muscle? If, on the other hand, Kulchitsky's view is correct and Hunter is correct in his conclusion that "the two muscular systems of invertebrates are represented as small groups which mingle together to constitute the skeletal muscles of vertebrates," may it be that the voluntary muscle-fibres or the nerve-fibrils which innervate them are secondarily involved? Gordon Holmes suggests[39] that the changes met with in the anterior horn cells in some cases of muscular dystrophy may perhaps be explained by supposing that "the terminal branches of the axis-cylinder, left naked by the disappearance of the muscle-fibres, will be probably injured and possibly destroyed by the connective tissue which proliferates secondary to the muscle disease." May it be that the voluntary nerve-fibrils are secondarily injured and ultimately destroyed by the changes in the muscle or in the interstitial tissue, the increase of the latter resulting not as a secondary process but, as I have suggested, as a direct consequence of disturbance of the sympathetic innervation? But if this is so, why is it the exception to find changes in the anterior horn cells? Here, again, I would refer to Gordon Holmes's suggestion[40] that—

> "The integrity of the nervous system in some cases of primary muscular atropby is parallel to the fact that sometimes all the ventral motor horn cells disappear after amputation of the segment of the limb which they supply, while in other cases these cells may be practically unaffected."

The enlarged muscles in pseudohypertrophic paralysis for long retain their power. May it be that the fat acts as a cushion or buffer and prevents strangulation of the voluntary fibrils which are only involved at a later date when, as the fat is absorbed, the muscle wastes?

MUSCULAR DYSTROPHIES AND ENDOCRINES.

The question of a relationship between the ductless glands and the myopathies has of late been referred to repeatedly in the literature, notably by the endocrinologists. References to this relationship from the neurological standpoint are, on the other hand, comparatively infrequent. The muscular dystrophies have not received much attention in this relation. Isolated clinical observations have been accumulating, but hitherto very few post-mortem examinations upon cases of muscular dystrophy have been reported in which special attention has been directed to the condition of the endocrines. In two cases studied anatomically by Goodhart and Globus,[42] the only pathological changes in the organs of internal secretion were observed in the thymus, while Clarke and Atwood[41] found in one case an enchondroma of the hypophysis. Pathological observations are necessary in order definitely to establish the suggested relationship on a sure basis.

I shall now direct your attention to certain observations which seem to me to suggest that there is a relationship between disturbance of pituitary function and the muscular dystrophies. I may commence by citing briefly the leading facts of a case in which pseudohypertrophic paralysis was associated with adiposity and defective sexual development.

W. M., aged 11, was admitted to my care on the recommendation of Dr. Andrew Rutherford. The youngest of a family of five, none of his relatives so far as is known have been similarly affected. Always somewhat stout, at the age of 6 he was operated upon for an acute appendicitis. At that time it was first noticed that he was easily knocked over and often fell when walking, and at the same time he began to increase greatly in weight. The muscular weakness has been steadily progressive.

The patient is very stout. His height is 4 ft. 1 in., his weight 7 st. 13 lb. The mammæ are somewhat prominent and there is a definite mons veneris. Although he is said to have been rather backward at school his intelligence appears to be little, if at all, below the average. The genitals are poorly developed, the testes being very small and soft. Headache has not been complained of. The visual acuity, the fields of vision, and the fundi (examined by Dr. H. M. Traquair) show no abnormality. The total quantity of urine for the 24 hours averages 24 oz. The fasting blood-sugar, taken on two separate occasions, was 0·108 per cent. and 0·113 per cent. The sugar tolerance could not be determined. The basal metabolic rate was +11 per cent. on June 1st, 1925; −14 per cent. on Oct. 28th, 1925. Examination of the fæces shows 33 per cent. of fat in the dried stool (split 57 per cent., unsplit 43 per cent.). The systolic blood pressure is 112, the diastolic 90. X ray examination shows no enlargement of the sella turcica or other obvious abnormality. Further, there is a pronounced atrophic paralysis with a typical distribution as met with in pseudohypertrophic paralysis, affecting particularly the muscles of the shoulder-girdle and trunk, the upper arm muscles, and thighs. The muscles below the elbow, notably the extensors of the wrist (the brachioradialis was absent), as also the muscles below the knee, especially the anterior tibial group, show pronounced weakness. There is very definite enlargement of the calf muscles, but on account of the adiposity it is not possible to determine whether there is enlargement of other muscles.

When two uncommon pathological conditions coexist in the same individual the question naturally arises: Is the association accidental or is there some relationship, and, if so, what is it? I have been able to find records of similar cases reported by Foerster, of Breslau,[43] Dziembowski,[44] and McCouch and Ludlum.[41] I have also heard of two further cases as yet unpublished. Fœrster refers to the frequency of adiposity and high sugar tolerance in muscular dystrophy. I can personally recall two or three cases of pseudohypertrophic paralysis, seen many years ago, in particularly fat children, and it is, I think, very probable that these would nowadays be regarded as cases of pituitary adiposity. Gardiner-Hill, I. Jones, and Forest-Smith[45] have recently reported 60 cases of adolescent pituitary obesity "in which the primary disturbance seems to be one of pituitary function," a fact which indicates that this condition is far from uncommon. It is, indeed, probable that slighter degrees of pituitary adiposity are often not recognised. Again, it may well be that the muscular weakness may be overlooked in cases in which the glandular symptoms are pronounced. Dr. John Thomson recently mentioned to me a case of pseudohypertrophic paralysis in which the patient became very stout, an observation which would suggest in this case at least a special tendency to put on fat.

But it is further of interest to note that cases have been described by Eulenberg, Marquard,[46] Timme,[47] and Janney, Goodhart and Isaacson[48] in which appearances suggestive of acromegaly occurred in association with muscular dystrophy, a rather striking fact in view of the age of these patients. The following case of muscular dystrophy in which the patient's appearance is suggestive of acromegaly is of interest in this connexion.

J. A., aged 18. A younger brother suffers from pseudohypertrophic paralysis, and a sister has symptoms of rib pressure. A maternal uncle was dumb and is said to have walked in a similar manner to the patient. At the age of 7 the patient developed measles, and from that time his lower limbs and arms became progressively weaker. There is no definite history of enlargement of the muscles. Two years ago people began to remark upon his changed appearance, and he himself noticed about that time that his face was becoming larger.

The patient is somewhat childish. His height is 5 ft. 4 in., his weight 11 st. 13 lb. His features are coarse and large, the lower jaw is long and heavy, the lower teeth project above the upper and are set widely apart; the lips are thick and the mouth very large. The palpebral fissures are narrow, the nose broad and flat, the eyebrows and eyelids thick, the tongue large. There is a large simple goitre. The scalp is very mobile, the hands and feet are thick and broad. The hair is thick and coarse, and there is an excessive growth of hair below the knees. There is a good growth of pubic hair which extends upwards towards the umbilicus. The genitalia are rather infantile. The visual fields show no abnormality. X rays of the skull show no enlargement of the sella turcica or frontal sinuses. The average amount of urine passed during the 24 hours is 37 oz. The heart is somewhat enlarged to the left, but the sounds are pure. The systolic blood pressure is 135, the diastolic 95; sugar tolerance is diminished. The distribution and features of the muscular atrophy are typical of the later stages of pseudohypertrophic paralysis.

All these observations suggest that disturbances of pituitary function are met with in cases of muscular dystrophy with a comparative frequency which cannot be accounted for by coincidence.

A relationship between the pineal gland and muscular dystrophy has been suggested by Timme[47] who, in reporting four cases of "a somewhat atypical muscular dystrophy rather resembling Erb's infantile type," states that "the probability approaches pretty closely to proof that disturbances of the pineal gland play an important rôle in the pathogeny of progressive muscular dystrophy." I cannot here discuss Timme's interesting observations and conclusions. I may say, however, that he attaches considerable importance to "changes in the pineal gland demonstrated by roentgenology." Again, when an endocrine disturbance is met with in association with a muscular dystrophy, may it not be that both are dependent upon a common cause? Cases of muscular dystrophy associated with a pluriglandular disturbance have been reported by Claude[49] and by Brock and Kay.[50]

A hypoglycæmia has been noted by several observers in cases of muscular dystrophy. Thus Janney, Goodhart and Isaacson report nine cases of muscular dystrophy in all of which there was a definite hypoglycæmia. They remark that—

> "The constant presence of hypoglycæmia and the evidence of delayed glucose utilisation in muscular dystrophy make it probable that defects in carbohydrate metabolism are intimately connected with, if not directly causative of, the metabolic picture of the disease. . . . It seems likely that the muscles in this condition undergo weakness, atrophy, and degeneration as the supply of their carbohydrate pabulum is interfered with."

McCrudden and Sargent,[51] who have studied a case of muscular dystrophy with hypoglycæmia in great detail from the laboratory point of view, are of opinion that the hypoglycæmia may underlie the great fatiguability. Again, Goodhart and Globus, who also emphasise the association of hypoglycæmia with muscular dystrophy, hold similar views. But while these observations are of much interest further facts are required, for my own experience leads me to doubt the constancy of hypoglycæmia in muscular dystrophy.

NATURE OF THE PROCESS.

If, as I have suggested, the muscular dystrophies are determined by disease of the sympathetic, what is the nature of the process? If the sympathetic is selected by disease, is it not reasonable to assume that it may be affected by different pathological processes as are the somatic neurons? Is it not possible, for instance, that the sympathetic neurons may not only degenerate but that they may be picked out by selective poisons? Here, however, we are on the boundaries of a field of which we have little if any knowledge. Cases of recovery from muscular dystrophy have been reported by Erb,[52] Marina,[53] Jendrassik,[54] and others. The diagnosis between pseudohypertrophic paralysis and a toxic neuritis may on occasions, notably in the absence of a family history, give rise to great difficulty. This was so in a case which I have reported elsewhere.[55] In this case the late Dr. F. E. Batten, who was in doubt as to the cause, finally committed himself to a diagnosis of pseudohypertrophic paralysis, and the patient eventually recovered. So far as I know, in all the reported instances in which recovery has occurred, the cases were isolated, no other members of the family having been similarly affected. Is it possible that in these cases of reported recovery from muscular dystrophy the process may have been a toxic neuritis which has selected the sympathetic neurons and thus produced an atrophic paralysis similar in distribution to that met with in the muscular dystrophies? Whereas may it be that the familial cases are determined by a degenerative process, a tendency for the sympathetic neurons to die an early death? I am, however, fully aware that speculation has its limitations.

CONCLUSIONS.

1. The generally accepted view according to which the muscular dystrophies are regarded as myopathies or primary diseases of muscle is a negative conception.

2. There is very considerable evidence which would appear to suggest that the skeletal muscles in man have a dual innervation—a somatic supply concerned with movement, a sympathetic supply with fixation. The suggestion is advanced that the muscular dystrophies may perhaps be determined by disease of the sympathetic supply to skeletal muscles.

3. The muscles especially predisposed to suffer in the muscular dystrophies are: (*a*) those which develop early in the fœtus; (*b*) those which are regressive (in the sense that they no longer fulfil such an important function as in an earlier stage of evolution) as opposed to those which have been acquired at a later date or have taken on new functions; and (*c*) those especially associated with the function of fixation. A difference in function suggests a difference in innervation.

4. The histological appearances met with in the muscular dystrophies are more easily accounted for by postulating a common cause than on the assumption that the process is a primary one affecting either the interstitial tissue on the one hand or the muscle on the other. An analogy is drawn with the tabetic arthropathies in which both hypertrophic and atrophic changes are met with.

5. Symptoms are observed in the muscular dystrophies which cannot be explained by a primary disease confined to the muscles. This would suggest that the atrophic paralysis of the muscles is merely the most prominent manifestation of a more widespread process.

6. It is suggested that the gradual loss of power and wasting may be determined either as a direct consequence of interference with the sympathetic innervation or as a consequence of secondary involvement of the somatic nerve fibrils by the changes in the muscles and interstitial tissue which result from disease of the sympathetic nerve-supply.

7. The suggestion is advanced that cases of muscular dystrophy in which great improvement or recovery has occurred may perhaps be explained by a difference in the nature of the pathological process. While the familial cases may be due to an abiotrophy of the sympathetic neurons, these isolated cases may conceivably have been determined by a toxic neuritis which has selected the sympathetic fibres and produced an atrophic paralysis of similar distribution.

8. Pseudohypertrophy, when it occurs, is an individual rather than a familial characteristic. It is here suggested that it may possibly be a superadded phenomenon dependent upon relative pituitary insufficiency.

9. Facts are submitted which appear to indicate a relationship between disorders of the pituitary gland and the muscular dystrophies. It may be that disturbances of the pineal and other glands also occur. The probability would appear to be that both conditions are due to a common cause rather than that the muscular dystrophy is secondary to the endocrine disturbance.

DR. SCHWEITZER'S HOSPITAL FUND.—Some eleven years ago Dr. Albert Schweitzer, musician and medical missionary, opened a hospital at Lambarene in French Equatorial Africa specially for the treatment of sleeping sickness and leprosy. Early last year he returned to Africa with the object of starting a second hospital in the Cameroons, full facilities being provided by the British Government. Circumstances then prevented the carrying out of the project, but an appeal for help has recently been made by a British council, of which Dr. P. Manson-Bahr is the medical member, in order that Dr. Schweitzer's work may be extended. British Bulletin No. 1 explains the reasons why it should be possible to establish a hospital in British territory at Nyasoso. Up to Sept. 10th last £128 had been received in contributions. Anyone who desires to receive further bulletins should send name and address to Miss M. O. Bronner, hon. treasurer of the fund, at 15, Castleton Mansions, Barnes, London, S.W. 13.

THE SPECIFIC TREATMENT OF PNEUMONIA.

By J. STAVELY DICK, M.B., B.Ch. R.U.I.,
HON. CLINICAL PATHOLOGIST, HOSPITAL FOR SKIN DISEASES; LATE PATHOLOGIST, NORTHERN HOSPITAL; AND TEMPORARY HON. PHYSICIAN, ANCOATS HOSPITAL, MANCHESTER.

There is little doubt the treatment of pneumonia at the present time is more chaotic than that of almost any other ailment. Some cases are treated with orthodox stock mixtures; others with some drug or combination of drugs in which the prescriber has faith; some believe in poultices, others in icebags. Specific treatment is not uncommonly given without any serious attempt to ascertain whether it is in fact specific—in other words, the precise nature of the infection is inferred, not demonstrated.

Serums and vaccines have revolutionised the treatment of some serious or intractable diseases, but opinions are still sharply divided on the question of their value in pneumonia. There seems, however, to be a fairly general consensus of opinion that specific treatment is more likely to be of decisive value if employed as a first, not as a last, resort. Wynn reports that of 107 cases of influenzal pneumonia 28 were treated with pneumococcal vaccine on the first day, and all recovered; whereas of 20 cases so treated on the fourth day of the disease five died. Lister, from a wide experience in South Africa, is in favour of vaccines in early cases, given in larger doses than we have been accustomed to in this country. He has demonstrated experimentally that the blood serum of rabbits develops specific antibodies after suitable doses of pneumococcal vaccine, and that rabbits so treated resist infection by living and virulent pneumococci, whereas rabbits not so protected invariably die. Lister seems to have definitely proved that prophylactic inoculation of pneumococcal vaccine reduced the incidence of pneumonia.

I have been using pneumococcal vaccine regularly for 15 years as opportunity offered, and, though I have had cases in which this treatment seemed to have no effect, I feel strongly that every incipient case of pneumonia or doubtful "influenza" should be treated with pneumococcal vaccine without delay. If vaccine is given as a routine in doubtful "influenzal" attacks, before definite physical signs are present in the lung, the results will often be so good that we are subsequently in doubt whether we have been dealing with an incipient pneumonia or not. For example:—

Case 1.—Some years ago I was asked to see a patient in consultation a little before midnight. The doctor in attendance had, with another medical man, come to the conclusion in the afternoon that the patient was suffering from incipient pneumonia. When I saw him his temperature was about 104° F.; he had a well-marked malar blush. His illness began some 12 to 18 hours before my visit. All the evidence available was in favour of the diagnosis already made. I gave him a medium dose of pneumococcal vaccine; and it was arranged that the three of us should meet in consultation the following afternoon. We did so, and were astonished to find that a complete transformation had occurred in the interval. His temperature was normal: his pulse had also fallen; but, fearing that he might not make an uninterrupted recovery, I took a blood culture, with a view to preparing an autogenous vaccine if necessary. The culture was negative.

A wider experience has shown that a negative result might have been anticipated. It is now clear that I should have taken a blood culture when his temperature was high the night before. If this had revealed a pneumococcal infection there would have been no doubt as to the nature of the illness, and little doubt as to the value of the treatment adopted. Of course, it may be argued that a negative blood culture does not exclude a pneumococcal infection. I quite agree: but it seems to me that for the purpose of establishing this treatment on a firm basis only positive cases should be considered.

Diagnosis by Hæmoculture.

Diagnosis by hæmoculture is more frequent than it was a few years ago; but I doubt whether its advantages and limitations are even now generally appreciated. A septicæmia is probably always present during the first few hours of a pneumonia. When this septicæmia persists to the later stages, and is associated with a comparatively low leucocyte count, I have found that the prognosis is bad, though the patient's general condition may seem fairly hopeful. Hæmoculture in pneumonia has recently become more important for treatment also. When positive it is the most convenient and rapid method for ascertaining the type of pneumococcus present, as a preliminary to the use of the Rockefeller serum in Type 1 cases. But this septicæmia is, as a rule, transient; it usually disappears in a day or two in cases of moderate severity. Fortunately, it is present most frequently at the stage when we are most in need of help in diagnosis and guidance in treatment. Besides, a positive blood culture permits of the earliest possible preparation of an autogenous vaccine.

As evidence of the comparatively transient character of the septicæmia in pneumonia, I may recall a case I published ten years ago. It came under observation during the incubation period, the only case of the kind I have seen. It is also relevant in this connexion as it was treated with pneumococcal vaccine on the first day of the fever.

Case 2.—A man, aged 46, consulted me in the evening on his way home from work. His pulse was 92; temperature normal (? or subnormal); he had no pain or other sign of a serious illness, but I was well acquainted with him, and, though I could find nothing wrong, I believed him when he said he *felt* ill, as he was paler than usual, with a distinctly "pinched" expression. Next morning I found his temperature 102° F.; pulse 108; respirations 40. Pneumococcal vaccine was given at once, and at the same time a blood culture (10 c.cm.) was taken; this yielded a profuse growth of pneumococci. Next day there was some improvement, but on the third day of the fever his temperature again touched 102° and his respirations 48–50. There was now some cyanosis, and for this reason some blood was taken from a vein and 10 c.cm. of it used for a second culture. This culture was sterile, though the patient was obviously in a serious condition. A larger dose of vaccine was now given, and next day (the fourth day of the fever) the following observations were made: Morning: temperature, 102°; pulse, 120; respirations, 58. Evening: temperature, 98°; pulse, 76; respirations, 54. The respirations continued high for several days, and there was still some delirium and restlessness. His pulse, however, never rose again above normal, and the temperature only touched 100° one evening. He has remained in good health up to the present time (1925).

I suggest that in this case there is a reasonable presumption that the natural course of events was modified by the vaccine. If this view be accepted it follows, I think, that this method of treatment should be tried on a larger scale than hitherto in incipient cases; but I venture to urge that hæmocultures are indispensable until conclusive evidence of the value of the treatment is forthcoming on a large scale. A mere multiplication of results similar to that recorded in Case 1 can hardly be expected to settle the question. I have had a number of results similar to that in Case 2 in the last 15 years, and many others are recorded in papers by Harris, Morgan, Raw, and Wynn. My experience points mainly to the necessity for prompt treatment of incipient cases. I can cordially endorse Dr. Wynn's dictum that early pneumonia "should be regarded as an acute medical emergency demanding prompt action in the same way that a perforated duodenal ulcer and acute appendicitis are regarded as acute surgical emergencies."

The treatment of incipient pneumonia is the concern mainly of the private practitioner, for it is he who is faced with these emergencies. The consulting physician sees them at a later stage, often, indeed, so late that specific treatment, if employed at all, is not given a reasonable chance. But material for a final assessment of the value of specific treatment in early pneumonia can hardly be anticipated from the isolated efforts of individual private practitioners under present conditions. If pneumonia were dealt with on similar lines to diphtheria as regards diagnosis, specific treatment, and notification the outlook would be more promising. In connexion with pneumonia, however, I suggest that it would be desirable not only to provide pathological facilities and vaccine or serum, but also some sort of clearing-house, preferably as a department of the public health service, which would collate clinical records. This would eventually permit of a sufficiently wide scrutiny of results to settle the matter to the satisfaction of all except perhaps the occasional crank who refuses to be influenced by evidence.

Conclusions.

I may summarise my conclusions as follows: (1) A medium dose of stock pneumococcal vaccine is free from risk; it appears to be of decisive value in many incipient cases; it should be used with the least possible delay. (An autogenous vaccine or Rockefeller serum involves some delay; they can be used later, if required.) (2) Any estimate, favourable or unfavourable, of specific treatment is comparatively worthless where the diagnosis is based solely on clinical evidence. (3) Hæmocultures are more frequently positive in incipient pneumonias than in the later stages; when positive at the onset they are helpful in treatment as well as diagnosis; when positive in the later stages they provide one of the most reliable foundations for accurate prognosis.

LIPIODOL IN THE DIAGNOSIS OF PREGNANCY.*

BY DR. CARLOS HEUSER,
BUENOS AIRES.

SINCE the discovery of X rays efforts have been made in different maternity hospitals to obtain radiographs of the fœtus during pregnancy, in order to make diagnosis clear and to throw light on conditions not recognisable by ordinary clinical methods. This problem has been partly solved by the newer apparatus, for it provides us with rays of such quality as to allow the taking of radiographs of the fœtus after the third month of pregnancy. These rays comprise a certain percentage of hard and white rays, from which must be eliminated the secondary rays and the reflections produced by the Potter Bucky diaphragm, in order to obtain a picture of the bony structure of the fœtus. There is no other way to make clear or to confirm a diagnosis in the early stages; X rays are absolutely indispensable for the diagnosis of a twin pregnancy, an anencephalous fœtus, or a dermoid cyst in case of non-appearance of the period for the first month or two. The exact appreciation of a pelvis narrowed in its different diameters can only be had after a good radiograph, and all the cases diagnosed by us have been successfully operated upon, for, before starting operation, we knew exactly what we had to deal with.

Apparatus and Method.

The best method of taking a good radiograph is to use a modern equipment—an apparatus which produces 100 kilo volts, 80 milliampères, tube Müller, Metro, or Medor, double reinforcing screen, films Victor, &c. These are the elements that must be relied upon in order to give a full measure of security. The photographer's art is indispensable in these cases in order to obtain the highest possible definition and clearness. It is also of great importance to have the bowels evacuated and that the fœtus and patient should be motionless. A purgative and an enema must be given the day before the radiograph is taken, and on the day of examination another enema is given with 40 drops of laudanum (Sydenham) in 50 c.cm. of water, and 10 to 20 drops are given to the patient one hour before the radiograph is taken. In this way a successful radiograph may be obtained from the fourth month of gestation.

Radiography Before the Fourth Month.

What I am about to explain is something different, something essentially new—viz., the taking of radiographs before that stage, a method entirely my own. It was perhaps by a scientific inspiration that, after the injection of lipiodol into the trachea, as used by Prof. Sergent, I conceived the idea of adopting the method with the uterine cavity, and so making possible a diagnosis of pregnancy. When a period or two is missed you can never be quite sure that a patient is pregnant, for the uterus might be small or it might be ante- or retro-flexed. In such cases a precise diagnosis is only possible by the use of X rays to show whether the cavity be occupied or not. In the different pregnant patients in whom we have injected lipiodol into the uterine cavity we did not provoke an abortion, while, on the other hand, the radiograph has enabled us to arrive at a positive diagnosis.

Usefulness of the Method.

In these conditions we have laid down fixed rules. When a woman after conception, and after one or more missed periods, wants to know if she is pregnant, and the clinical examination is indecisive, lipiodol must be injected into the uterus. A radiograph should then be taken in order to give absolute certainty. Under no other conditions must we proceed, in order to avoid dangerous eventualities.

If the injection has been successfully made the radiograph of the uterine cavity filled up with lipiodol shows: 1. That the cavity is not well filled if the fœtus is more or less developed, the lipiodol penetrating round the fœtus, and showing that the cavity is occupied. 2. The round shape of the stain with the radiograph of a tube together with the clinical symptoms indicating the pregnancy. 3. When the fœtus is larger, the liquid penetrates very little, in a line more or less curved, and the form of the radiograph of the uterus indicates the pregnancy. 4. If the period is missed once or twice and the patient thinks herself pregnant, the injection of lipiodol into the uterine cavity may show in triangular shape and at the same time one or both tubes may fill up with the liquid. In such a case the radiograph shows that the uterine cavity is unoccupied and there is no pregnancy. 5. Every radiograph of the uterine cavity must be complete in order to show the neck and cavity for a satisfactory diagnosis to be made from it, together with the clinical symptoms. 6. The radiograph may thus allow us to diagnose sterility due to obstruction of the tubes; for it may be observed that they do not fill or fill up badly. 7. In cases of pyosalpingitis and old salpingitis a radiograph of the tubes can be obtained and the diagnosis confirmed.

The procedure to be described is entirely new and is submitted now to others for the test of further experience. Hitherto we have had no means of trustworthy diagnosis of pregnancy in the first months. The problem is a serious one, for in all maternity homes there are records of cases of early pregnancy which have been operated on for fibroma. The injection of lipiodol into the uterus does not provoke abortion if definite rules are observed.

Technique of the Method.

We have applied this method in the case of all our patients who have presented themselves without any special selection and without any disturbance further than a careful disinfection of the vagina and the bladder. For that purpose we give, before taking the radiograph, a mild laxative in order to clean out the bowels; at the same time we douche the vagina with rivanol and instil twice a day silver nitrate solution or choleval into the bladder if there be cystitis. Four hours before we give 20 to 30 drops of opium, in order to keep the patient quiet. On the day of the injection we clean the vagina with liquid formalin soap, we brush the neck of the uterus with tincture of iodine, and with the most careful antiseptic precautions we introduce a large metallic cannula into the uterine cavity until the Brandt ring can pass. Then we inject 1 to 2 c.cm. of lipiodol, we take the radiograph, and inject, if possible, another 2 to 5 c.cm. and take a second radiograph. At the same time, if a better radiographic picture is wanted we inject 40 to 60 c.cm. of air into the bladder. The patient must be lying on her shoulders and in the Trendelenburg position.

---

* Presented at the London Congress of Radiology.

In the cases in which diagnosis is doubtful between a tumour and pregnancy we inject the first day 2 to 5 c.cm. of lipiodol, and the following day we inject air into the tubes in order to cause a pneumoperitoneum of 150 to 200 c.cm., the patient being in the Trendelenburg position. Afterwards we inject 5 to 10 c.cm. of lipiodol in order to show the uterine cavity. We use the liquid warm, without employing much force, with a light pressure, and without moving the cannula within the uterus.

During the injection the eyes of the patient must be observed, for the pupil is dilated when the liquid enters the tubes. The pupillary reaction is characteristic. When the injection enters the tubes it produces a little colic, and first there is a dilatation and afterwards a contraction of the pupils. If the woman has had salpingitis, this reaction is much stronger, but the passing of the liquid through the tube does not cause any pain. The lipiodol runs all over the uterine walls and penetrates into the tubes if these are free, but if they are obstructed on account of a former salpingitis they do not fill up. In these cases it is necessary to persist with the injection once or twice more in order to get them filled.

In cases where we wish to know if the tubes are permeable, whether for the diagnosis of sterility or of salpingitis, the technique is different. In these cases we previously empty the bowels, make the patient urinate, and give her 30 drops of opium in some water one hour before. Then we introduce 10 to 20 c.cm. into the uterus with a big cannula, the neck of the uterus being well closed in order to avoid the passing of the lipiodol into the vagina. The lipiodol fills up the uterus and passes into the tubes. If the lipiodol drops out into the vagina we repeat three or more times, until we are sure that it has passed. Before taking the radiograph we fill the bladder with air. In the cases of salpingitis the tubes do not fill up with the first injection; and it is necessary to repeat the injection until we obtain a good radiograph.

By this procedure it is possible to find out the causes of sterility in women, whether that be obstruction of the tubes or malposition. In cases where the tube is twisted the radiograph will give us a clear view of all details. If we are confronted with a tumour of doubtful nature we induce pneumoperitoneum by the ventral way or by way of the tubes, and then the injection of lipiodol is made into the tubes and the radiograph taken, the patient being in the Trendelenburg position. By this means the clear space in the pelvis due to the pneumoperitoneum reveals the tumour of the uterus and the relations of both with other organs.

Finally, I wish to mention that in Buenos Aires Dr. Uslenghi, Dr. Martinez, and the author have tried to provoke abortion in tuberculous patients by this means when it was indicated, but we did not succeed.

Corrigendum.—In the legend to Dr. C. C. Chesterman's illustration of the effects of tryparsamide in sleeping sickness (THE LANCET, Nov. 7th, p. 966) the word "tryparsamide" where it twice follows "ago" should read "trypanosomes."

A CASE OF
POLYCYTHÆMIA RUBRA RELIEVED BY X RAY TREATMENT.

BY S. W. PATTERSON, M.D. MELB., D.SC. LOND.,
PHYSICIAN, RUTHIN CASTLE, NORTH WALES.

THE case about to be described has been under close observation for 12 months, and is of interest because of the great improvement effected by X ray treatment applied to the long bones of the limbs, with the object of arresting overproduction of blood. It is suggested that the method may also be useful in treating certain cases of high blood pressure.

Clinical Record.

The patient was an unmarried woman, aged 42, whose mother died of Bright's disease at 38, and the father at 48 of "meningitis." During life his appearance and symptoms were similar to those of his daughter. The patient had had no severe illnesses until 1919, when she first noticed a blotchy non-pruritic rash on the left forearm. In April, 1919, she had two attacks of what was thought to be a severe nettle-rash of the face. The blotches on the left forearm came at intervals, but in other respects she was well till May, 1921, when she felt giddy and sick, and fell in the street. About a month later she woke one morning and felt a sharp pain down the left side of the head and left arm; the arm was numb and the hand has been weaker since. The power is gradually coming back, but the fingers are still weak. At that time the left knee-jerk was found to be exaggerated, and there was some staggering on walking. Headache and giddiness increased gradually. In the autumn of 1923 she noticed swelling and numbness of the left hand; and when examined in Paris in November, 1923, the blood was found to contain 7½ million red cells per c.mm. and blood pressure was 175 mm. Hg. The patient was put on a lacto-vegetarian diet with rests, and remained without much improvement till admission to Ruthin Castle in June, 1924.

On examination the face was high-coloured, fingers tended to be clubbed, and there was a blotchy, dark pink rash on the left forearm. The pulse was regular, of good volume, the artery wall not palpable during diastole, blood pressure 204/120 mm. Hg. The cardiac impulse was in the left nipple line, and the aortic second sound was accentuated. The electrocardiograph showed a normal P.-R. interval and an inverted T in lead III. The blood had 130 per cent. hæmoglobin measured by Sahli's apparatus, and contained 7 million red cells and 8000 white cells per c.mm. The differential count showed a normal distribution of these white cells. The viscosity of the blood was greatly increased; its withdrawal through a needle of ordinary bore was difficult and the blood clotted rapidly. There was no loss of power or altered sensation in the distribution of any of the cranial nerves, but distinct weakness and slight diminution in the circumference of the left arm and forearm. The muscles of the leg appeared normal. The knee-jerks were active and normal, and the left arm-jerks were increased in comparison with the right. Both plantar reflexes were flexor. Sensation to touch and pin-prick in left arm normal, but there was inability to name objects by touch (astereognosis).

The edges of the liver and spleen were firm and palpable. The urine contained 0·5 per cent. of albumin, and there were a few casts and epithelial cells in the deposit. The urea-concentration test was at the third hour 2·4 per cent., a low normal value. The basal metabolism rate was 100 per cent. of the normal. Sugar-tolerance curves for glucose and lævulose gave normal figures. The fractional test-meal showed super-acidity. X ray examination of the alimentary tract showed an abscess of the right upper premolar tooth, enlargement of the liver and spleen, and considerable delay in the colon. The diagnosis was made of essential polycythæmia rubra, with thrombosis of a vessel supplying the cortical centre for the left arm and hand.

Treatment.—The patient was treated as follows: The lacto-vegetarian (anticonstipation) diet, which had been taken for some time, was continued and the affected tooth removed. One grain of thyroid was administered twice a day and an intestinal douche twice a week. X ray treatment to the long bones was given twice weekly, on 25 days for 8 minutes each treatment, from July 4th to Oct. 17th, with the object of arresting the overproduction of blood. Diathermy was applied from hands to feet on the other 4 days a week, 12 minutes for each treatment, passing 800 ma. Fig. 1 shows curves of the blood count and blood pressure before, during, and after the treatment.

Clinically, the colour became normal, headache and giddiness disappeared, and the spleen was no longer palpable. A subjective feeling of well-being accompanied the return of the red blood cell count to normal. The urine still contained on April 21st, 1925, a faint trace of albumin. No casts were found. The electrocardiograph showed as before an inverted T wave in lead III.

It is now nine months since the treatment was discontinued. During this time the patient has remained well and repeated examinations have shown a normal blood count.

Results.—A steady improvement in the blood count, the blood pressure, and the clinical state took place when these measures were used. It will be seen that the red cells and hæmoglobin diminished to normal values, which have been maintained. At the same time the blood pressure fell to a normal figure.

Discussion.

The simultaneous fall in blood pressure to a normal level is striking. This fall may have been the result of diathermy treatment, but, from a comparison with a large number of other cases, I think this is unlikely. The blood was at first much more viscous than normal and was aspirated with difficulty through a needle. The increased viscosity itself is an explanation of the high blood pressure owing to the increased work which the heart must do in order to drive the viscous blood through the arterioles. Parkes Weber [1] has pointed out that many cases of polycythæmia show no rise of blood pressure, and attributes this to a compensatory dilatation of capillaries. Other possibilities are that adrenalin-like substances having a pressor action might bring about a raised blood pressure, and at the same time an inspissation of the blood, owing to greater perfusion of the watery constituents; but such a toxin would probably not have so continuous an effect. It may be that there is also excessive production of red blood corpuscles by a bone-marrow over-stimulated by some poison.

FIG. 1.

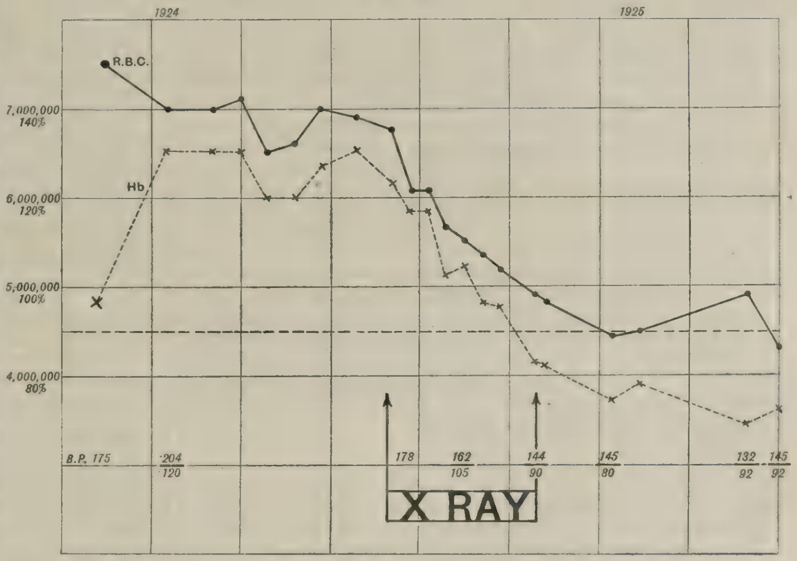

FIG. 2.

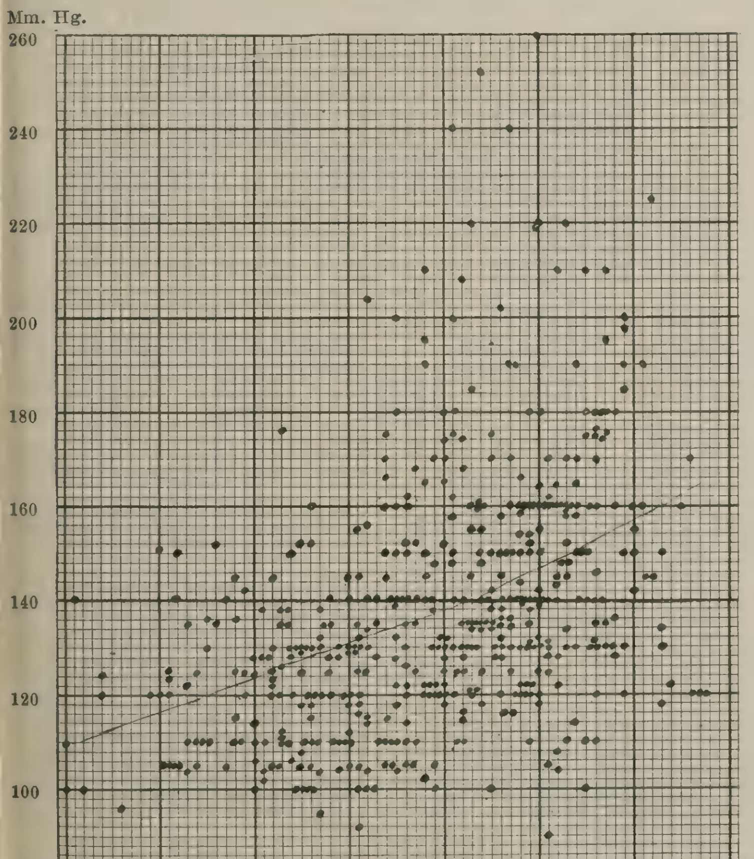

Suggested Use of X Rays in Cases of High Blood Pressure.

The successful result in the above case suggests that the application of X rays to the long bones may be of value in the treatment of high blood pressure. The red cell count in patients with high blood pressure may be above or below normal. Those showing counts above normal are often the subjects of early heart failure and show signs of cyanosis, but a certain number of patients with blood pressure above normal have been found to have a supernormal red cell and hæmoglobin count, apart from any failure of the heart. Patients with low red count are often the subjects of secondary renal disease. From the records of Ruthin Castle, of the last 41 patients with a systolic blood pressure of 180 mm. Hg or more, 19 had a red cell count and hæmoglobin above normal—i.e., nearly 50 per cent. The chart (Fig. 2) shows the systolic blood pressures of 489 cases at Ruthin Castle in relation to their age. There is, of course, a rise in the average systolic blood pressure with increasing years. Of those having a blood pressure above normal, 41 out of 84 had also a high red cell and hæmoglobin value, 29 being distinctly supernormal.

Patients suffering from hypertension have been greatly benefited by venesection and the removal of one-half to one pint of blood, but the good effect of this is only temporary, and it is suggested that a more lasting effect may be obtained by diminishing the red blood cells by applying X ray to the marrow in the long bones, in this way reducing the red blood corpuscles slowly and under control.

During the treatment of patients in the Frankfürter Frauenklinik by deep X ray therapy, Wolmershäuser [2] noted that 75 per cent. showed a fall in blood pressure which might amount to 50 mm. of mercury, and this fall occurred whether the patient suffered previously from hypertension or not. This was attributed to a dilatation of the skin vessels and possibly to increased vagus action on the heart.

The first patient on whom this method was tried was a married women, aged 52, who had been admitted on a previous occasion for high blood pressure, headaches, and attacks of giddiness. Under treatment for four months by diet, rests, graduated exercises, diathermy, baths, and venesection (three times), the blood pressure, which had been 240, was reduced to about 170–180. Soon after her return home the headaches and giddiness recurred, making her an invalid and calling again for venesection. She was readmitted to Ruthin Castle and the same treatment carried out with the addition of X ray exposures of the long bones twice a week. The blood pressure fell from 214 to 150–160 mm. Hg in two months, and the patient has been able to lead a comfortable though restricted life for the last four months. Recent reports give the blood pressure as still 150–160, although the hæmoglobin and red corpuscles have increased again.

Summary.

A case of essential polycythæmia rubra was treated successfully by exposing the long bones to X rays with the object of arresting overproduction of blood. It is suggested that the method may also be useful in treating certain cases of high blood pressure.

TWO CASES OF
ACUTE GLOMERULITIS.

BY S. C. DYKE, D.M. OXF., M.R.C.P. LOND.,
PATHOLOGIST TO THE WOLVERHAMPTON AND STAFFORDSHIRE GENERAL HOSPITAL.

THE picture of acute nephritis usually presented to students and practitioners alike in this country is that of a disease associated with œdema, hæmaturia, and albuminuria. It is, in fact, the clinical picture presented by either the "nephrotic" or "Misch" forms of nephritis of Volhard and Fahr,[1] the most recent systematic writers on the subject. This type of acute nephritis is by far the most commonly met with in practice; none the less, it is well to bear in mind that it is quite possible to have a very acute and fatal nephritis presenting no œdema at all in the clinical picture. Such a type of nephritis is the acute glomerulitis described by the German authors. It is probably not a common condition, though its rarity may be more apparent than real, since the possibility of its occurrence is seldom taken into account in the making of a diagnosis. These considerations serve as the reason for the publication of the cases described below.

Clinical Records.

CASE 1.—Female, unmarried, aged 22. In good health up to three days before admission. Sudden onset with abdominal pain followed on the second day by vomiting and severe headache. No urine was passed during the 48 hours preceding admission to hospital.

Condition on Admission.—The patient was drowsy and almost comatose; temperature normal; pulse 76. Blood was oozing from the gums and the head was retracted. The abdomen was rigid and both pain and tenderness were present in the epigastrium. Catheterisation resulted in the drawing off of a few ounces of blood-stained and highly albuminous urine. Death occurred on the day following admission, the patient up to that time having been running a temperature up to 102° F.

Post-mortem Examination.—The body showed no œdema, nor was any excess of fluid present in the serous sacs. The only organs showing any abnormalities were the kidneys; these appeared large, tense, and deeply congested; on section the capsule stripped readily, the cortex was increased in depth and dark in colour. Microscopically the kidneys showed no fibrosis and little round-celled infiltration, and no apparent abnormality of the tubular epithelium. Many of the tubules, more especially the convoluted, were stuffed with blood, coming apparently from the glomeruli, upon which the whole brunt of the pathogenic agent appeared to have fallen. The glomeruli were universally affected and all in the same way and to the same degree. The tufts were so swollen that they completely filled the capsular space; the normal differentiation of the tufts had disappeared and the nuclei appeared to be increased in numbers. Many of the tufts showed hæmorrhage. The endothelium lining Bowman's membrane in every instance showed some degree of proliferation, which in many cases had proceeded to the formation of pronounced "endothelial crescents." All the glomeruli showed collections of round cells about their periphery; in some instances these collections were fairly extensive, and where this was the case it was often apparent that the continuity of Bowman's membrane had been dissolved, and the inflammatory round cells had actually passed into the intracapsular space and were invading the tuft itself. Although all the glomeruli without exception showed signs of morbid change the tufts showed no inflammatory cells, except in those instances in which solution of Bowman's membrane had occurred. The appearances suggested that the vitality of the tufts had been universally damaged by some pathogenic agent, and that the invasion by round cells was occurring as the result of this devitalisation. The objective of the round cells appeared to be the tuft itself, but it would seem that they were unable to reach it until actual solution of the capsular membrane had been brought about.

CASE 2.—Female, aged 12. Had been in bed for two weeks prior to admission with diarrhœa and vomiting, becoming increasingly acute. At the onset there had been swelling of the face in parotid region on both sides, but this had subsided.

Condition on Admission (May 23rd, 1925).—Temperature normal, pulse 84; mouth and tongue very foul; patient almost comatose. There was general tenderness and rigidity over the abdomen; the urine contained much albumin.

Course in Hospital.—May 24th: Vomiting continuing. Condition otherwise unchanged. Only 5 oz. of urine passed. 25th: Bleeding commenced from mouth and gums and continued until death. A dark red morbilliform rash appeared, patchy in distribution, affecting face, trunk, and limbs alike. No urine passed. 26th: No urine passed; 2 oz. collected by catheter. 27th: Temperature still normal; pulse 96. The vomiting became violent, and blood was brought up in considerable quantities up to the time of death on the following day. No urine passed.

The results of the laboratory investigations on this case were as follows.

Urine.—May 24th: Much blood present, no casts or organisms seen. Albumin + + +; reaction acid; urea 1·64 per cent. 26th (catheter specimen): Much blood present, film shows numerous streptococci but no pus cells. Culture *B. coli* and streptococcus. 27th: Same as for previous day except that streptococci were obtained in pure culture.

Blood.—May 26th: Urea, 648 mg. per cent.; red cells, 5,580,000 per c.mm.; white cells, 36,700 per c.mm.: polymorphs, 95 per cent.; lymphocytes, 5 per cent.

Cerebro-spinal Fluid.—May 26th: No pleocytosis. Globulin slightly in excess (? due to contamination by blood). Sugar, 137 mg. per cent.

Post-mortem Findings.—Body was that of an emaciated and poorly developed female child showing the remains of a dusky rash on face, trunk, and limbs. Heart: Nothing abnormal. Lungs: Right lung showed some small localised patches of consolidation; left lung nothing abnormal. The liver, spleen, intestines, and brain showed no abnormalities. The stomach showed some areas of hæmorrhage into the mucosa, but no bleeding points from which the vomited blood might have come. Kidneys: Right 185 g., left 176 g.; both large, dark red, and tense. On section the capsule stripped readily leaving a perfectly smooth surface. The cut surface showed marked bulging; the cortex was greatly increased in thickness and somewhat pale in colour. The histological appearances of the kidneys were almost identical with those described under Case 1. The only difference was in the comparative lack of proliferation of the endothelium lining Bowman's membrane with a consequent rarity of endothelial crescents. These were present, but not nearly so plentifully as in Case 1. The tufts showed the same changes as in Case 1, but on the whole to a rather greater extent. Proliferation of the intracapillary endothelium was marked and degeneration had proceeded to breaking up and pyknosis of the nuclei.

---

Comments.

Case 2 corresponds fairly closely to the intracapillary type of glomerulitis of Volhard and Fahr, while Case 1 is a good example of the extracapillary type. These two cases, however, serve as illustrations of the fact that these two types are not really distinct entities, as each showed changes both of the extra- and intra-capillary types, though the relative distribution of the two types of lesion differed in the two cases. Owing to its rapid termination in death Case 1 was incompletely investigated. Considering, however, the close resemblance of the histological appearances of the kidney in this case to those shown in Case 2, it seems justifiable to assume that the results of the clinical laboratory investigations would have been the same. The blood-urea in Case 2 was very high, and presumably urea retention was also a feature in Case 1. This, of course, was to be expected in view of the almost complete suppression of urine. The blood picture in Case 2 is interesting; the high white count would seem to indicate an acute infection; the temperature, however, remained normal throughout. In Case 1 the rise of temperature to 102° F. just before death also points to the presence of an infective agent. The generalised morbilliform rash in Case 2 serves also to point to the activity of an infective agent. This rash occurs occasionally in cases of mixed glomerulo-tubular nephritis; curiously enough, such a case with rash happened to be admitted to the same ward a few weeks after the death of Case 2.

The presence of streptococci in the urine in very large numbers in Case 2 suggested that this organism might be the cause of the condition. The complete absence of pus cells from the urine, however, was strongly against this assumption. It seemed much more likely that the streptococcus was a saprophyte growing in the scanty stagnant urine; the presence of *B. coli* along with it lent support to this view, as also did the fact that the streptococcus was non-hæmolytic and gave the reactions of *S. fæcalis* (Holman). Careful search through sections stained with eosin and methylene-blue failed to reveal any organisms in either case, and on this evidence the streptococcus was definitely ruled out as an ætiological agent.

The combined evidence presented by these two cases none the less points strongly to the infective origin of acute glomerulitis. The absence of any pus cells in the cellular reaction occurring around the affected glomeruli would appear to rule out the pyogenic cocci as the causative agents, while at the same time the histological picture corresponds to that produced by none of the recognised pathogenic organisms. Granted the existence of an infective agent it would seem that it must be one of those not detectable by ordinary microscopic methods. The relationship of this extremely acute and rapidly fatal type of glomerular nephritis to the more common glomerulo-tubular type is open to question. It is possible that with a less overwhelming infection the course of the condition might have been slower, allowing for the appearance of the characteristic tubular changes. On the other hand, acute glomerulitis of the type described may be an entity in itself, bearing no relationship to the mixed form.

Summary.

Two cases of pure acute glomerulitis are described, both with fatal issue. Both cases were characterised by almost complete suppression of urine and complete absence of œdema. Evidence is adduced pointing to the infective nature of this type of case, though in neither of the two instances described could the causative organism be identified.

My thanks are due to Dr. T. H. Galbraith and Dr. E. H. Coleman, in whose beds the cases described were patients while in hospital.

Clinical and Laboratory Notes.

A CASE OF
UNDULANT FEVER CONTRACTED IN ENGLAND,
AND COMPLICATED BY HÆMORRHAGIC EFFUSION INTO THE PERITONEAL CAVITY.

By C. R. Box, M.D., F.R.C.P. Lond.,
SENIOR PHYSICIAN TO ST. THOMAS'S HOSPITAL AND THE LONDON FEVER HOSPITAL;

AND

J. Bamforth, M.D. Liverp., M.R.C.P. Lond.,
ASSISTANT BACTERIOLOGIST, ST. THOMAS'S HOSPITAL.

As a condition arising in this country undulant fever is sufficiently rare to command attention. There appear to be few such instances in the literature, but one was reported by Byam[1] in 1918. The following case presented unusual features.

The patient was a male, aged 28, by occupation a draughtsman. His family history revealed nothing of import. During the war he served in France, and was inoculated with T.A.B. vaccine in 1916. While in France in 1917 he suffered from trench fever and influenza, but there was nothing to suggest that during this period he suffered from undulant fever. Early in October, 1923, patient was staying in the country, and whilst there on one or two occasions drank raw goat's milk. A few days later he returned to London, and about the middle of October, ten days or so after partaking of the milk, his illness began. This incubation period of ten days corresponds to that usually described. The first symptoms noticed were severe night sweats, rise in temperature, and a general feeling of unfitness. A week later both hip-joints became stiff and painful, and a little later still the left wrist was painful and swollen. At the end of a fortnight, however, both hips and wrist had returned to normal, but pains in the shoulders followed and these in turn passed off. The night sweats became worse, and his temperature taken on two successive nights was 104° F. This condition continued, and he was admitted to St. Thomas's Hospital on Jan. 1st, 1924, at the request of his medical attendant, Dr. R. C. P. Whitcombe, who suspected undulant fever.

Condition on Admission.—The patient was anæmic, and had obviously lost a considerable amount of weight. The pulse was 96, regular, full and easily compressible. The heart sounds were normal, and there was no evidence of cardiac enlargement. No abnormal physical signs were found in the chest. The spleen was just palpable. The urine had a sp. gr. of 1020, acid, and contained neither albumin nor sugar. The illness proved to be long and tedious.

After admission the fever continued, with headaches and night sweats varying in intensity from time to time. On Feb. 6th it was noticed that the abdomen was becoming distended. There was tenderness over the spleen and dullness on percussion in both flanks. About the 10th the fever began to subside, but the abdominal distension slowly increased, and on the 15th 50 c.cm. of a dark hæmorrhagic fluid was withdrawn for examination. The distension, however, became more and more marked, and on the 26th 8½ pints of similar fluid were withdrawn. Following paracentesis the patient showed a marked improvement in the general condition, the severity of the symptoms diminished, and though a certain amount of fluid was left in the peritoneal cavity this was slowly and gradually absorbed, until, on examination on March 24th, the abdomen appeared normal. He also began to gain in weight. At the beginning of April, however, a relapse occurred, the temperature rising, and frontal headaches and night sweats returning with their former intensity. There was no recurrence of the arthritis or ascites.

On May 3rd, 1924, the patient was discharged from hospital at his own request, and since discharge he appears to have made rapid improvement, as in a letter received months later, in April, 1925, he states that his temperature has been normal since July, 1924, and that he is in good health and able to do his work without difficulty.

Bacteriological Examination.

A blood examination was undertaken on Jan. 2nd, 1924, the day after admission. The total leucocyte count was

---

[1] Byam, W.: A Case of Malta Fever arising in England, THE LANCET, 1918, i., 873.

3480 per c.mm., of which 56 per cent. were polymorphs, 24 per cent. large lymphocytes, 10 per cent. small lymphocytes, 9 per cent. large hyalines, and 1 per cent. mast cells. The blood serum gave an agglutination with typhoid antigen at a titre of 1/100, with para. A at 1/50, but with para. B and C there was no reaction. These results were presumably attributable to the T.A.B. inoculation in 1916. The serum was found to agglutinate both *M. melitensis* and *B. abortus* antigens at a titre of 1/2000, which end-point is as high as that of the artificial serum prepared at the laboratory. A blood culture done on the same date proved subsequently, however, to be sterile, and two further blood cultures made at later dates were unsuccessful. Cultures were also made from the urine of the patient obtained on Jan. 4th, but *M. melitensis* was not cultivated, and two guinea-pigs inoculated with the urine intraperitoneally showed no ill-effects, and six weeks later were quite normal. The hæmorrhagic fluid from the abdomen was also examined. It contained a large amount of blood. Of the leucocytes 60 per cent. were lymphocytes and 32 per cent. polymorphs, and many showed vacuolation and other degenerative changes. The supernatant fluid after centrifugalisation agglutinated both *M. melitensis* and *B. abortus* to a titre of 1/1000. No organisms were found in films made from the centrifuged deposit, and none were grown in culture. Inoculation of a guinea-pig was without result, and the animal was in normal health three months later. It was subsequently killed and examined, but no evidence of tuberculosis or other disease was found.

A sample of milk from the goat was obtained for examination. Both the whole milk and the whey gave agglutination reactions with *M. melitensis* to a titre of 1/250 and with *B. abortus* to 1/500. Cultures made from the milk with a view to isolating the causative organism were unsuccessful.

Remarks.

The character of the fever in this case did not show such marked undulation as usually obtains in this disease. The occurrence of ascites with hæmorrhagic fluid was remarkable, and led to a suggestion, which was, however, disproved, that the patient was, after all, suffering from tuberculosis. It is possible that the effusion was associated with thrombosis of the portal vein, and in this connexion it is noteworthy that enlargement of the liver with jaundice and ascites has been seen by several observers, and is generally found late in the disease. It is interesting to note that several other persons, in addition to the patient, drank some of the goat's milk, but none of them contracted the disease.

LARGE MESENTERIC CYST IN AN INFANT.

REMOVAL; RECOVERY.

PHYSICIAN, ROYAL MANCHESTER CHILDREN'S HOSPITAL;
AND
John Morley, Ch.M. Manch., F.R.C.S. Eng.,
HON. ASSISTANT SURGEON, MANCHESTER ROYAL INFIRMARY.

This case is of interest on account of (1) the difficulty of diagnosis, (2) the successful result of an operation that was only undertaken as a forlorn hope on account of the great size of the tumour and the age of the patient, and (3) the pathology of the cyst.

A. L. D., a male infant, aged 4 weeks, sent by Dr. Sinclair Couper (Blackpool), was seen on Feb. 23rd, 1922, with a large tense, fluctuant swelling in the abdomen. The swelling had been present at birth and had grown steadily larger. There had been no vomiting and the bowels were regular. The child had been fed on dilute cow's milk and had lost ground in the last two weeks, during which slight œdema of the feet had developed.

Condition on Examination.—The baby was thin, with a strong cry. A round smooth swelling, very obvious on inspection, filled the whole abdomen except the left lower quadrant. The tumour was tense, fluctuant, and dull on percussion. Since the colon could not be palpated in front of it, the swelling plainly did not originate in the right kidney, but origin from the liver could not be excluded. As the swelling was evidently cystic, it was thought that operative measures might have a remote chance of success.

Operation (Feb. 24th, 1922).—Under nitrous oxide and ether anæsthesia, by Dr. K. B. Pinson, with preliminary subcutaneous infusion of normal saline, the abdomen was opened through the right rectus. A huge cyst was disclosed lying behind the peritoneum, with a coil of ileum stretched over the front of it. The liver and gall-bladder above it were normal. The cyst was punctured on the right side in a non-vascular area and some pints of clear fluid evacuated. The resulting collapse enabled one to see that the cyst was in the lower mesentery and had pushed the cæcum up into the left hypochondrium. The cyst wall was thick and muscular, and lined with a whitish membrane. Enucleation of the collapsed cyst was carried out gradually without tearing any of the main blood-vessels supplying the bowels. The dissection was tedious on account of a copious supply of small blood-vessels to the cyst and the friable nature of the cyst wall. When the entire cyst had been removed, the space between the two leaves of the mesentery was drained by a tube and the incision in the peritoneum sutured up to the tube. The abdominal wall was closed in layers.

Subsequent Progress.—Repeated subcutaneous salines were given for the first 24 hours, during which period the child showed signs of collapse. The tube was removed in 24 hours, and from the second day a steady improvement began, in spite of a superficial infection of the wound. In four weeks from the operation the child returned home in good condition with the wound healed. He has since grown into a strong and healthy boy.

Pathological Report.—The entire cyst was submitted for examination to Dr. (now Prof.) B. J. Ryrie, of the Department of Pathology, Manchester University, who reported as follows:—

> Many sections of the cyst wall were examined. All showed a muscular and fibrous tissue wall; some showed definite epithelial lining. The different layers constituting the cyst wall were unequally developed in different parts, but the total structure, as seen in the most fortunate sections, consisted of: (1) a thick outer layer of unstriped muscle cut transversely; (2) a thin layer of connective tissue; (3) an inner layer of unstriped muscle parallel to the plane of section; (4) a layer of connective tissue of varying thickness tending to merge gradually with a more vascular and more cellular subepithelial connective tissue layer; (5) a lining layer of columnar or cubical epithelial cells.
>
> The outer muscular layer was generally well developed. It showed varying degrees of fibrosis and hyaline change. The inner muscular layer was more variable. It was never entirely absent, but was in parts very largely replaced by fibrous tissue. It also showed areas of hæmorrhage, hyaline degeneration, and calcification. These changes tended to involve also the inner layers of the cyst wall, causing ulceration and calcification at the free inner surface. Such degenerating areas also were invaded by mononuclear or more often polymorphonuclear leucocytes, giving a more cellular appearance to the area and obliterating the structure of the wall. The epithelial layer was very patchy and imperfect. At one point it could be seen to dip down into the subepithelial connective tissue, but there was no true gland formation. The specimen was apparently an enterogenous cyst, with secondary degenerative changes in its walls.

C. N. Dowd,[1] in a well-known article on mesenteric cysts, gives a simpler classification of these cysts than earlier writers. He groups them into (1) embryonic cysts, (2) hydatid cysts, (3) cystic malignant disease. The varieties described as chylous, serous, and hæmorrhagic cysts he would regard as being of embryonic origin. He believes that the embryonic cysts arise either as rests from the ovary at an early stage of intra-uterine life, as in the case that he himself describes, or from the intestine.

There appears to be no room for doubt as to the enterogenous nature of the cyst in our case, and its position suggests that it may have arisen from the vitello-intestinal duct after the manner of a Meckel's diverticulum, becoming shut off, however, from all communication with the intestinal lumen. Higgins and Lloyd,[2] in a recent paper, consider that enterogenous mesenteric cysts arise more commonly from sequestration of diverticula from the intestine other than Meckel's diverticulum, but the fact that these cysts are found more often in close relation with the ileum than with the higher reaches of the small intestine appears to us to support an origin from the vitello-intestinal duct.

Medical Societies.

HARVEIAN SOCIETY.

AT a meeting of this Society held on Nov. 12th, with Sir JOHN BROADBENT, the President, in the chair, Dr. J. D. ROLLESTON read a paper on the

Differential Diagnosis of Scarlet Fever and Diphtheria and Modern Methods of Treatment and Prophylaxis.

He illustrated the similarity between the two diseases by the fact that it was little over 100 years since Bretonneau distinguished between scarlatinal and diphtheritic angina and established diphtheria as a specific disease, and it was only since 1861 that deaths from diphtheria, as distinct from those due to scarlet fever, had appeared in the returns. At the present time the difficulty in distinguishing between the two diseases was shown by the large number of cases sent to fever hospitals certified to be suffering from diphtheria or concurrent scarlet fever and diphtheria, when they were really examples of scarlet fever pure and simple. In the course of a year 47 cases had been sent to one fever hospital certified as diphtheria, but were found, after admission, to have scarlet fever instead. Dr. Rolleston laid stress on the fact that diphtheria and scarlet fever coexisted much less frequently than seemed to be supposed. He had often noticed that his junior colleagues showed an excessive zeal in cultivating the throats of scarlet fever patients in the acute stage, regardless of the fact that more or less faucial deposit was the rule in scarlet fever of any severity. In a case of scarlatinal angina in which organisms were found morphologically resembling diphtheria bacilli, the virulence test should be applied before assuming that the case was one of concurrent scarlet fever and diphtheria.

Owing to the remarkably mild type of scarlet fever now prevalent in London it was exceptional at the present time to see a case of scarlet fever with severe angina. A severe epidemic of the anginose type of scarlet fever had occurred in Yunnan (South China) in 1921–22 and had caused 50,000 deaths in the capital Yunnan-fu alone. The disease had at first been mistaken for diphtheria and treated by antitoxin, especially as the rash was often absent or so slight as to escape attention. Apart from bacteriological examination, the chief distinctions between the appearances of the troat in scarlet fever and diphtheria were, as Bretonneau pointed out, first, that in scarlet fever the inflammation was widely diffused over the tonsils, palate, and pharnyx, and was not, as in diphtheria, circumscribed to one spot; secondly, that the inflammatory process in scarlet fever, except in a late stage of septic cases, showed no tendency to attack the larynx; and thirdly, that scarlatinal angina was liable to be attended by more or less considerable ulceration which was usually absent in diphtheria. The condition of the mouth and tongue was often of some diagnostic assistance. In scarlet fever they were usually in a dirty condition with strings of mucus between the tongue and the palate which interfered with a good view of the fauces. The general condition was also of some help in diagnosis. Scarlatinal angina was accompanied by continuous pyrexia and delirium, whereas in diphtheria the temperature, though it might be high at first, rapidly fell to normal, especially after injection of antitoxin, and the mind remained clear. The therapeutic test was often of considerable value. When in a case of supposed diphtheria the temperature tended to keep high in spite of repeated injections of antitoxin, the probability was against the angina being diphtheritic in nature and there was a greater likelihood, though by no means a certainty, of the case being scarlet fever.

Prophylaxis and Treatment.

In dealing with prophylaxis Dr. Rolleston emphasised the fact that scarlet fever was not nearly so infectious a disease as some of the other acute exanthemata, especially measles and small-pox. It was through inability to realise this fact that too much importance had been assigned to the Milne method of inunction of the skin with eucalyptus oil and the application of 1 in 20 carbolic oil to the tonsils, which had lately been proved by Dr. Milne's successor, Dr. G. Gushue-Taylor, to be valueless. After giving a short account of active and passive immunisation against scarlet fever and diphtheria, Dr. Rolleston said that the most important principles in the treatment of diphtheria were injection of antitoxin and enforcement of rest. The earlier the antitoxin was given the better the results. He had never known a patient die of diphtheria or even suffer from severe paralysis when antitoxin had been injected within 24 hours of the onset. Late cases required relatively large doses of antitoxin, and it was a mistake to suppose that antitoxin was useless after the fifth day, as had been alleged. In a series of 160 cases injected with antitoxin on admission to hospital after the fifth day the mortality was only 11·2 per cent., whereas in the pre-antitoxin era, even when patients were brought under treatment at the commencement of the disease, the mortality was never less than 28 per cent., and not infrequently rose to 50 per cent. or more. The presence of membrane in the throat, however late the disease, was an indication for serum treatment, the doses ranging from 4000 to 12,000 units in mild cases to 18,000 to 24,000 repeated two or three times in severe attacks. Intramuscular injection, preferably in the vastus externus, was the best method of administration of antitoxin for the following reasons: (1) it was quite as simple as the subcutaneous method, it ensured more rapid absorption, was less painful, and less liable to give rise to abscesses at the injection site; (2) it was superior to the intravenous route not only in the greater simplicity of technique, but also in the less rapid excretion of antitoxin after injection. Intravenous injection was accompanied in a large proportion of cases by rigors, vomiting, and collapse, and did not in practice, whatever its theoretical superiority might be, appear to have any advantage over the intravenous method.

In only a comparatively small proportion of cases—namely, 16·5 per cent. in a series of 2000—had Dr. Rolleston found it necessary to employ local treatment of any kind. From comparative observations he had found that the average period for the throat to become clean after injection of antitoxin was practically the same whether local treatment had been employed or not. The time that a patient should be kept in bed should be determined by the character of the acute attack. After mild angina this period need not be more than three weeks, but in attacks of any severity the recumbent position should be enforced for seven or eight weeks at least as being the best safeguard against paralysis. An exception could be made in the case of infants who never sat up unless they were fit, and therefore need not be restrained from so doing. Dr. Rolleston maintained that there was no justification for the routine administration of alcohol in diphtheria, as recommended by some authorities, especially in view of the fact that it was generally recognised by scientific clinicians that it had no stimulant action on the heart, respiration, or vital activities in general, while its continued use was liable to increase the myocardial degeneration initiated by the diphtheritic poison.

Discussion.

Dr. R. A. O'BRIEN referred to the usefulness of the Schick test in the diagnosis of diphtheria. Every patient admitted with frank clinical faucial and laryngeal diphtheria gave a positive response to the Schick test, and on examination his blood would be found to contain no detectable antitoxin. Thus, for a definite diagnosis of clinical diphtheria in any instance of special interest, one would be entitled to ask proof that the patient was "Schick positive," that he had no antitoxin in his blood, that the course of the disease was typical, that the smear from an overnight culture made from a swab showed a preponderance of diphtheria bacilli, and that these bacilli proved to be virulent. In a number of instances reports had been received that people who were negative to the Schick test had afterwards suffered from frank clinical diphtheria. In every instance which the speaker had the opportunity of investigating it had been found that the Schick test result had been wrongly recorded, in some instances through the use of diluted toxin many months old, or that the clinical diagnosis was in error. With regard to the recent prohibition of active immunisation in Vienna owing to the Baden accident, the mixtures the speaker and colleagues had worked with had for a year or two past been made of toxoid and antitoxin. The toxin was first deprived wholly, or almost wholly, of its toxicity by treatment with formalin; it was then diluted ten times and a considerable amount of antitoxin added. The mixture still remained an efficient immunising agent and was, so far as test and experience went, a "safe" one. There was apparently some slight misunderstanding about the position of active immunisation in New York. In the course of health propaganda which was always going on in that city, it had recently been pointed out by the health authorities that the immunisation of children of school age was of great value, but that as a very large percentage of diphtheria occurred in children of pre-school age the time had now come for the public to realise that effort must be directed more especially towards the immunisation of young children through welfare centres, nurseries, &c. Active immunisation had, in the opinion of people in America, proved itself as a valuable aid to public health and it would be even more vigorously recommended to the public. The campaign had recommended itself to the financial judgment of insurance societies who had contributed considerable sums of money to the work.

Dr. C. C. OKELL gave a short description of the recent work of the Dicks and Dochez on scarlet fever and discussed some of the problems that have arisen from it. There was a possibility that more than one type of scarlet fever toxin might exist, but as yet there was no definite evidence on the point, and it was much more likely that the toxin was always the same. Five strains carefully examined by cross-immunity experiments showed no essential differences in the properties of their toxins. The practical bearings of the modern work on actual practice could be summarised as follows: (1) The Dick test divides those who are susceptible to scarlet fever from those that are not. (2) Active immunisation with toxin renders Dick-positive persons Dick-negative and presumably non-susceptible. (3) Potent antitoxic serum can be obtained in the horse which in 5 c.cm. doses temporarily renders Dick positive persons Dick-negative and which in 40–50 c.cm. doses has a definite therapeutic effect on cases of scarlet fever. The newer knowledge had also an application to diagnosis, since early rashes of scarlet fever were for the most part blanched by intradermic injections of either horse antitoxin or of serum from convalescent patients. The Dick test itself was almost always positive in the first 48 hours of the disease.

Dr. GRAHAM FORBES confined his remarks to the subject of diphtheria and the question of the practicability of immunisation on an extensive scale in so large a centre as London. The recent decision of the London County Council not to include that preventive measure at present in their scheme of medical treatment of school-children was not unexpected in view of the difficulties which the problem presented in the matter of the numbers to be dealt with, quite apart from anticipated parental objections. Further, results were also awaited of the immunising work, chiefly in residential institutions, being done by the Ministry of Health and various local authorities in Great Britain, where up to date it was estimated that in all about 22,000 of the population had been Schick tested and some 4000 immunised, inclusive of 4500 of tested and 2000 immunised in the Edinburgh schools—figures which provided insufficient data in comparison with the high totals supplied by New York; there, since 1920, roughly half a million had been tested and one-third of the school population had been immunised. The outcome of such widespread prevention was being watched with the greatest interest, but the results were not yet regarded as entirely conclusive. Time would doubtless show how far immunisation was proving effective in the reduction of the incidence and mortality of diphtheria in New York. The decline in 1922 and 1923, which seemed to point to a marked improvement, had not apparently been maintained in 1924 and 1925.

New York.

Year.			Cases.		Mortality per 10,000 population.
1921	..	..	15,000	......	16·0
1922	..	..	10,000	......	15·0
1923	..	..	8,050	......	9·0
1924	..	..	9,687	......	11·9
1925 (6 months)	..	..	6,056	......	14·9

Dr. O'Brien, however, had informed him that the recent rise in New York had been forecast by Dr. Park as likely to be associated with a concomitant prevalence of measles, and to be expected from the large number of susceptible children, of former pre-school age and not previously immunised, now entering school and, therefore, coming in closer contact with possible infection. The example set by the Borough of Holborn, thanks to the initiative of the medical officer of health, seemed to point a way to obtaining the more widespread prevention of diphtheria in London if adopted by the authorities of other metropolitan boroughs.[1]

Considered from the purely financial aspect, it had been estimated that diphtheria alone in 1921 had cost the ratepayers no less a sum than £500,000. Even if it were possible or necessary to test the whole of the elementary school population (some 600,000) and immunise, say, 40 per cent., reckoned as susceptible, the total cost, he calculated, would not exceed a tenth of the sum spent on the present system of hospital isolation, treatment, and home disinfection. Therefore, by the introduction of immunisation, there was to be added to the hope of saving life and averting sickness the prospect of reducing heavy public expenditure.

BRITISH INSTITUTE OF PHILOSOPHICAL STUDIES.

THE Institute opened its winter session on Nov. 19th at the London School of Economics with a discussion on the

Idea of Responsibility, Legal and Medical.

The chair was taken by Mr. HAROLD LASKI, and Sir TRAVERS HUMPHREYS, opening the discussion from the legal side, limited his field to the medical aspect of legal responsibility and the criminal responsibility of a person for his own acts. A lawyer's business, he said, was to obey the law and not to criticise it, and he would therefore simply state the law of responsibility and the theory which he understood to underlie it. It was for the doctors to say what the law ought to be.

The Mens Rea.

The criminal law of the country was based on common sense, and the broad principle of responsibility was that a prisoner was regarded as responsible for his acts unless it was proved that he had not acted with a "mens rea," a criminal intent. A person would not be held responsible if he committed a crime in a state of somnambulism or hypnotism (unless he had himself hypnotised for criminal purposes), nor was he liable for an injury resulting from pure accident, though if a serious injury happened where a trivial one were intended he was held responsible because of his intent to harm. It had been found, however, in the course of legal evolution, that there was a class of criminals to whom this principle could not be applied; either they did not know what they were doing or else they thought that their action was perfectly lawful. They were thus legally "not guilty," but it was in the interests of society that they should be restrained from repeating the offence. These people were usually insane, and it became customary to record a special verdict in such cases, when the judge would order the accused to be detained for the state of his mind to be examined. This practice was subsequently regularised by law.

---

[1] See THE LANCET, Nov. 7th, p. 962, Dr. C. W. Hutt: Diphtheria Immunisation in a Metropolitan Borough.

The McNaghten Ruling.

Insanity was notoriously difficult to define; many people were mentally unsound in some respects and not in others, or situated on the border-line. The famous McNaghten ruling was not new law, but merely a restatement of what had been legal for many years. The same principle was enacted in an Edinburgh trial of 1795. To plead ignorance of the nature of a serious crime was, of course, practically to plead insanity.

The Uncontrollable Impulse.

It had often been urged that the law should excuse a person who could prove that he committed a crime under the influence of an impulse which he was unable to control. The law certainly admitted no such plea at present, as a recent judgment of the Court of Criminal Appeal had emphatically declared; the Court further expressed the opinion that such a plea would have a subversive effect on justice. It seemed to be put forward only in murder cases. The difficulty in its application was the practical impossibility of establishing the fact of uncontrollable impulse by evidence.

Dr. **William Brown** spoke from the medical aspect of the question, and pointed out that the doctor could not escape from the problem, as the lawyer could, by disregarding all but the intellectual factor and making it an axiom that volition was the only test of responsibility for an act. An emotional factor had also to be considered. Many crimes were committed by people who knew well the nature and quality of their act, but who were nevertheless irresponsible through mental disorder. He instanced epileptics, melancholics, maniacs, and alcoholics. In a post-epileptic condition a butcher or soldier might commit a crime of violence through performing what was to him a habitual act. A melancholic who believed that ruin or torture were about to befall his family might deliberately murder them to save them from a worse fate, while the paranoiac might kill those whom he suspected to be plotting against him. Both would feel convinced that they were perfectly justified.

Individuals such as kleptomaniacs and exhibitionists knew that they were doing wrong, but suffered from compulsions so strong that the power of control of the normal man was insufficient to keep them in check. Psychological analysis showed that the events and phantasies of childhood and the repressions associated with them accounted for the impulses, so that in one sense the individual was responsible, but often less so than those who had brought him up. Responsibility must be put on the right persons, and collective responsibility was often as real as personal responsibility and as rigidly exacted.

The Question of Insanity.

Legal responsibility inevitably introduced the question of insanity as only the insane were held not responsible. Insanity was not a scientific concept; the scientific distinction was between the normal and the abnormal. Certification and legal "insanity" were concerned only with whether the individual were a danger to himself or others and depended to some extent on social position. To define abnormality was to enter the realm of metaphysics; science had to stop short of the problems of determinism and freedom, and assume that an individual's actions were explicable in terms of his heredity and antecedent acts. A normal man might be regarded as one whose whole heredity and life was a continuous progress towards the synthesis and harmonisation of his impulses. Most people, however, were abnormal, and the question was how far the law could take account of their abnormalities. At present it did so in terms of knowledge only. He wondered whether it would be a sufficient proof of uncontrollable impulse if the accused showed that he had had a deep analysis which revealed the source of these impulses. He illustrated his meaning from war-time court-martials on deserters. The phrase "tout comprendre est tout pardonner" was entirely wrong. Understanding made one realise the patient's difficulties but not think less of the crime. Responsibility was a matter of degree; a person in robust health was more responsible than an invalid. Psychologists did not want to abolish responsibility, but to redistribute it.

Discussion.

Mr. M. **Ginsberg** said that responsibility was intimately connected with punishment, and the only true test of responsibility was whether the man was capable of knowing at the time that he might be punished for it.

Mr. D. **Carswell** said that the McNaghten judgment had been abandoned in Scotland since 1870. He did not see that metaphysics and psychology had much to do with the question; it was for the jury to decide whether, considering a prisoner's mental state, it was fair to punish him.

Dr. T. B. **Hyslop** declined to attempt a definition of insanity until the lawyers had defined responsibility. In his experience the question of responsibility was never put to a medical witness. A sane man might commit a crime under the influence of hypnagogic hallucinations, and he had known an epileptic hanged for murder. What might be good law was bad medicine, and he regarded the McNaghten ruling as an effete judgment.

Dr. **Brown**, in reply, said that a man might be responsible to something beyond society, to his conscience, his ideals or his ideas of the cosmos, and that society might condemn him and be right according to its limited view of the situation. The distinction between the fanatic and the prophet was part of the work of deep analysis, which might thus help to solve the problem of responsibility.

ULSTER MEDICAL SOCIETY.

At a recent meeting of this Society, Mr. J. A. **Craig**, the President, in the chair, Prof. J. E. **MacIlwaine** read a paper on

Hyperpiesia.

The speaker gave Allbutt's definition of hyperpiesia as essential or primary arterial hypertension and discussed the mechanism of its possible production, dealing with the rôle played by the nervous system, cerebro-spinal and autonomic, together with the vascular musculature and the associated myoneural junctions. He referred to the experimental production of the condition by hormones, adrenalin, pituitrin, and by protein metabolites such as guanidin, tyramin, and emphasised the variable relationship to true arterio-sclerosis as well as the distinct separation of hyperpiesia from the hypertension of renal disease. Special stress was laid upon the hereditary tendency as well as the association of the condition with a history of vasomotor instability in early life. The endocrinic adjustment occurring at the menopause was cited to illustrate the part these glands must play in the hyperpiesia of this period of life. The signs and symptoms which may be complained of were briefly recapitulated, and it was pointed out that in many cases they were so vague as to be indefinitely classed as neurasthenic. Referring to a previous paper read before the Society upon nervous mechanism in disorders of the circulation, the speaker restated his assumption that in disordered action of the heart we had a toxic or inherent manifestation of instability in the autonomic nervous system which might be classified as a neurasthenic syndrome. To-day in the knowledge of the close association of psychic, psycho-motor and autonomic nervous system with the endocrine activities we might use a similar theoretical conception of an instability of this great controlling mechanism as a practical basis for the treatment of hyperpiesia. To relieve stress on this mechanism wherever possible should be the ideal, and he emphasised the primary importance of attention to the demand made by the assimilation of food on the autonomic nervous system.

Dr. S. Boyd Campbell read a paper on

Aortitis, its Prognosis and Treatment.

The speaker, after referring to the frequency of a syphilitic ætiology in aortitis, showed a series of 35 cases which were first seen in 1919–20. All of these cases had at that time definite signs of varying degrees of aortic dilatation, in some cases definitely aneurysmal in character. Of the 35 cases 7 died; in 5 of these the death was associated with œdema and cardiac failure, and in 2 death was due to a ruptured aneurysm. Signs of failure of compensation are always of grave import. Antisyphilitic treatment, he said, depended on the case. In active lesions iodides and later small doses of mercury were used. Arsenical preparations should be given in small doses, starting with 0·3 g. If patient was kept in bed the dose was increased to 0·45 g., but if the patient was treated as an out-patient the 0·3 g. dose was not increased.

LIVERPOOL MEDICAL INSTITUTION.

At a pathological meeting held on Nov. 19th Mr. W. A. Thompson read a paper on

Pyloric Stenosis of Infants.

He gave a short résumé of the various opinions held on the pathology of the affection, and explained how even when the condition was present at birth it failed to give rise to symptoms immediately because the pylorus was still unobstructed; later, under the influence of feeding, retention occurred; this caused enlargement of the mucosa, which further closed up the pylorus and induced added spasm. This increased the hypertrophy and the vicious cycle thus created brought about pyloric obstruction. The time required for this sequel of events varied from a fortnight to a month. According to the severity of the obstruction so the symptoms varied. The mild cases should be treated medically, the severe cases operated upon at once; whilst he advocated early operation on all moderately severe cases, since by this means an anxious period from 6 to 16 weeks was eliminated and the child was operated on when it was in the best physical condition. He was convinced that if this were done the mortality from this affection would be very small, as the majority of medical and surgical deaths came from this group. He described Ramstedt's operation and emphasised the importance of giving saline intraperitoneally. Ether was the anæsthetic used at his operations. He had performed Ramstedt's operation on 21 occasions with 19 recoveries. The two deaths occurred in greatly debilitated children.

Numerous specimens were shown, including a spinal cord tumour with lipiodol injection, by Prof. John Hay and Prof. R. E. Kelly; an acoustic tumour removed without facial paralysis, by Dr. Henry Cohen and Prof. Kelly; carbolic acid gangrene of finger, by Mr. Ashcroft; carcinoma of a reascended testis by Mr. Frank Jeans; and simultaneous chorion-epithelioma and adenomyoma of the uterus, by Dr. A. A. Gemmell.

Stirling Royal Infirmary.—A new infirmary is to be erected at a cost of between £70,000 and £80,000, the existing building having become insufficient. A site of 15 acres has been acquired for £5200; the building fund now exceeds £52,000.

Reviews and Notices of Books.

The Surgery of Pulmonary Tuberculosis.

By John Alexander, B.S., M.A., M.D., Assistant Professor of Surgery in the Medical School, University of Michigan. Philadelphia and New York: Lea and Febiger. 1925. Pp. 356. 21*s*.

"This volume," says Dr. Alexander in his preface, "presents the entire subject of the surgery of pulmonary tuberculosis with the object of acquainting the medical profession with the principles and practical details that will enable it each year to save thousands of lives which certainly will be lost if surgery is not undertaken."

Dr. Alexander does, indeed, present the entire subject, and in a most thorough and painstaking manner. His book is not a record of personal experience—personal experience is, in fact, entirely omitted—it is an epitome of the experience of all the surgeons and physicians in the world who have interested themselves particularly in thoracic surgery. He has condensed the world literature, and from the number of his references we may gather that he has extracted the pith of 500 books, papers, and personal communications; he has also weighed and summed up the value of recent advances and of the various efforts that have been made towards further improvement in technique. His book, which is a great achievement, was awarded the 1925 quinquennial Samuel D. Gross prize by the Philadelphia Academy of Surgery.

Dr. Alexander emphasises the great need for a fuller understanding and appreciation of the value of the surgical methods available to-day. He says, with truth, that "there exists to-day among many physicians and patients a hazy notion that the shock and mortality from the 'rib operations' are terrific, the post-operative pain scarcely endurable, and the permanent clinical success a rarity. They believe that the survivors, grossly mutilated and crippled, may only hope to drag themselves through a few extra years of burdensome life. That the notion is not based upon fact will be evident to anyone who is informed on present-day technic and results." Dr. Alexander has collected 1159 thoracoplasties done during the period 1918–25. The results of these have been as follows: "Cured," 26·8 per cent.; improved, 24·4 per cent.; died from causes directly or indirectly connected with the operation, 13·2 per cent. There are, out of 1159 cases on whom the major operation has been done, nearly 500 "cured" or *greatly* improved. This is a remarkable record in view of the fact that scarcely one of these patients was expected to survive his disease by continuing with artificial pneumothorax and sanatorium régime. The author deals thoroughly with the indications and contraindications for the treatment he advocates. Artificial pneumothorax is compared with thoracoplasty, their respective merits being well summed up. Claus's epigram is quoted (p. 97): "A good pneumothorax is better than a thoracoplasty, but a good thoracoplasty is better than a bad pneumothorax." The following operative procedures all receive consideration: extrapleural paravertebral thoracoplasty (Wilms-Sauerbruch and Brauer methods); paravertebral thoracoplasty of the upper ribs combined with phrenicotomy, phrenicotomy, extrapleural pneumolysis, intrapleural pneumolysis, drainage of tuberculous lung cavity, tuberculous effusion and empyema.

The book should be read by all interested in the treatment of pulmonary tuberculosis.

Internal Secretions.

The Personal Equation. By Louis Berman, M.D. London: George Allen and Unwin. 1925. With 7 plates. Pp. 303. 8*s*. 6*d*.

Everyone who read "The Glands Regulating Personality" will remember the gaiety with which

Dr. Berman pursued his thesis that we are mostly the product of our endocrines and that by personalities and temperaments we may best be classified as pituitarians, adrenalists, and so on. He urges the same views in the present volume which in substance does not add much to his first book. And some of the zest seems to have gone from his exposition. It may be that the ideas are now less novel and exciting, but we cannot avoid a suspicion that the author's thyroid (or is it his pituitary ?) may be beginning to fail.

A Text-book for Midwives.

Fourth edition. By **John S. Fairbairn**, F.R.C.P., F.R.C.S., Obstetric Physician to St. Thomas's Hospital. London: Humphrey Milford, Oxford University Press. 1925. With 3 plates and 113 illustrations, 5 in colour. Pp. 365. 25*s.*

THE author states in his preface that the alterations in the present edition are solely confined to those necessitated by the recent revision of its rules by the Central Midwives Board and by the issue of the regulations regarding the lengthened training which will shortly come into force. These rules are incorporated in the text wherever they apply and when necessary an explanation is given of their rationale. This is a commendable innovation which will prevent the pupil from learning these precepts by rote without understanding their practical application. The book as it originally appeared contained more than was necessary for the midwife. Since that time the period of training has been—or is shortly to be—quadrupled. Presumably a higher all-round standard of knowledge will be now required by the examining body, but this text-book will meet modern requirements in every way and will not need to be supplemented by larger works. Antenatal hygiene, the management of the lying-in woman, and the feeding of the infant are adequately dealt with from a practical standpoint. The last-named section is particularly useful and constitutes one of the best accounts of infant feeding to be found in any text-book of midwifery.

Aphasia.

Kritische Studien zur Methodik der Aphasielehre. By **E. Niessl von Mayendorf.** Berlin: S. Karger. 1925. Pp. 108. M.6.

Dr. Niessl von Mayendorf's latest contribution to the aphasia problem takes the form largely of destructive criticism. It is divided into three parts, dealing respectively with the methods of localisation of Prof. S. E. Henschen, the question of agrammatism, and the theories of Prof. G. Mingazzini. In regard to the first of these, Henschen's view, briefly, is that lesions of the lower end of the left ascending frontal gyrus produce dysarthria, not aphemia (Broca's motor aphasia); lesions of the posterior end of the third left frontal convolution (pars opercularis frontalis) produce motor aphasia. Von Mayendorf is at pains to collate and analyse a number of the cases relied on by Henschen and to endeavour to show they cannot possibly bear the interpretation put on them by the latter. The view he advocates is that since words are commonly aroused in the auditory speech areas, it is unnecessary to postulate a motor speech centre apart from these; the defect of speech of many lower frontorolandic cases is simply the result of interruption of the path from the auditory area to the motor centres for innervation of the speech musculature. Dealing next with agrammatism, the author criticises adversely the well-known views of the late Prof. Arnold Pick, and concludes that agrammatism is nothing else than paraphasia, or, rather, is no more than the syntactical form of paraphasia. He adopts the view that both dysarthria and agrammatism (paraphasia) are restitution phenomena which appear "after the first acute stage of amnesia verbalis kinæsthetica is over." Finally, the views of Mingazzini, that in the lenticular nucleus is a "centre" disorder of which produces dysarthria or anarthria, and that in the frontal centrum ovale just outside that nucleus and extending across and in front of the internal capsule to the head of the caudate nucleus is an area lesions of which cause word-dumbness, are submitted to analysis in the same way as in the case of Henschen's views—viz., by an independent scrutiny of the cases on which Mingazzini largely depends. The conclusion is reached that of 22 cases supposed to favour Mingazzini's theories, not fewer than 21 also showed right hemiplegia, whence it is argued that "lenticular" theories are entirely unnecessary.

The matter of von Mayendorf's monograph does not lose any of its impressiveness by the emphatic and forceful, not to say caustic, language with which the arguments are clothed. His own theories, it may be pointed out, are, in respect at least of the non-existence of a special motor speech area apart from the rolandic centres for innervation and of agrammatism, open to no little criticism themselves. But his communication serves a useful purpose in drawing attention to the complexity of many recorded cases from which authors have unjustifiably made deductions of a pleasing simplicity to support favourite views of their own.

Schistosomiasis vel Bilharziasis.

By **C. G. Kay Sharp**, Chief Medical Officer, Education Department, Province of Natal. With a Foreword by Dr. J. B. **Christopherson.** London: John Bale, Sons and Danielsson, Ltd., 1925. Pp. 74. 7*s.* 6*d.*

THE incidence of urinary schistosomiasis in Natal and Zululand is a high one—in school-children, for instance, it may be 13 per cent.—though the severity of the disease appears to be not so great as in Egypt. Contrary to the general opinion, schistosomiasis is not confined to the coastal belt, for several cases recorded in this booklet have been contracted 4000 feet above sea-level and 150 miles inland from the coast. The intermediary hosts of the schistosome in South Africa are *Phyopsis africana* and *Limnœa natalensis.* Few original views are expressed in this volume; the greater part is a compilation of the work of others and includes substantial quotations from popular text-books, while the section on treatment lacks such practical details as are required by the general practitioner. Not many of the illustrations are original. The absence of any scale showing the magnification of cercariæ is a defect, and the omission of a good illustration of the egg of *Schistosoma hœmatobium* is unfortunate. However, in directing attention of medical officers in Africa to the outstanding features of this disease and its method of spread a publication of this nature will serve a useful purpose.

The Sleeping Child.

Über den Schlaf des Kindes. By Dr. **Paul Karger**, Privatdozent for Diseases of Children in the University of Berlin. Berlin: S. Karger. 1925. Pp. 50. M.2.40.

A BRIEF introduction on the general characters of the sleep of the normal child, with its more or less normal periods of alternating quietude and movement, its depth and duration, and with an interesting discourse on the night movements of plants, animals, and man, is followed by a series of personal investigations of an objective kind on the sleeping child in health and disease. An apparatus resembling in part the familiar self-registering barometer was used, the recording point on the drum, which moved by clockwork at the rate of 4 cm. an hour, being connected up by a simple method with the framework of the bed or cot. Every movement of the child communicated a vibration to the bed which was thus recorded on the graph. A large series of these are reproduced in the book, and their comparison is instructive. The effect of various hypnotics and sedatives was also thus graphically measured. The method is practically useful and capable of extension.

COLLOIDS.

An Introduction to the Physics and Chemistry of Colloids. Fifth edition. By M. L. HATSCHEK. London: J. and A. Churchill. 1925. Pp. 183. 7*s.* 6*d.*

THIS well-known little book was first published in 1923, being based upon a series of lectures delivered by the author at the Sir John Cass Technical Institute. Until quite recently it was the only small English text-book upon the subject. Within the last few months some rivals have entered the field, but Dr. Hatschek's volume is far too well established to fear competition. The volume deals with colloidal chemistry as a whole, and provides a readable introduction to a complicated subject. The new edition has been brought quite up to date, and includes a lucid account of the work of Porter and Hedges on the vertical distribution of particles and more importantly of the recent work upon absorption. The theories of L. Michaelis, Freundlich, and J. Loeb are carefully considered; indeed, we find no omissions of any consequence and the balance is well maintained.

Laboratory Manual of Elementary Colloidal Chemistry. Second edition. By M. L. HATSCHEK. London: J. and A. Churchill. 1925. Pp. 153. 7*s.* 6*d.*

THE subject of colloidal chemistry is usually taught by means of lectures, with possibly a few demonstrations. The student hardly ever performs experiments himself; the difficulty of devising an adequate course may partly account for this lack of practical work. The object of Dr. Hatschek's laboratory manual is to provide a book of elementary instructions for practical classes; the course prescribed is well suited to the needs of elementary, general, and medical students, since the experiments are arranged so as to lead to a definite sequence of ideas. After an introductory chapter on apparatus, exercises on dialysis are described. Correct details are given for the preparation of dialysis membranes, and for the carrying out of a series of experiments upon typical colloids. The student is then taken through the preparation of typical suspensoid sols, suspensions, and other general properties. Ultra filtration, Tyndall phenomenon, and the electrical behaviour of colloids are dealt with in a series of simple illustrative procedures. The principles of absorption and the Liesegang phenomenon are also described with examples. Everywhere the accounts are accurate and instructive, and there can be no doubt that this book, which has now reached its second edition, is a worthy companion to the volume noticed above.

IMMUNO-CHEMICAL STUDIES.

Edited by CARL H. BROWNING, Professor of Bacteriology in the University, and Director of the Laboratory of Clinical Pathology, Western Infirmary, Glasgow. London: Constable and Co. 1925. Pp. 239. 12*s.* 6*d.*

THE objects of this volume are carefully defined in the preface by the editor, Prof. C. H. Browning; it is intended as a summary of the work of the Glasgow school upon the humoral aspects of immunity. Practically the whole of the information contained in the book has been published in various journals by the contributors. In many cases the articles are reprinted almost word for word, but the editor believes that their collection under one cover is likely to be appreciated by workers in this field. The volume opens with an introductory chapter by Prof. Browning upon antibody action in general. This consists of a summary of the general principles of immunity, and of the chemical basis of the reactions so far as known. The succeeding chapters consider in detail the factors of immunity, such as the properties of antigens and antibodies, opsonic action, and the final chapter deals with complement. The subject is difficult, and one which lends itself readily to confusion. In this volume, by means of careful classification and excellent summaries at the end of each chapter, the editor and contributors have kept the argument clear. The references are well selected and will be of great value to anyone engaged in immuno-chemical researches. The volume as a whole represents an admirable and laborious piece of work.

HYPERKINESIS.

Der hyperkinetische Symptomenkomplex und seine nosologische Stellung. By Dr. KURT POLISCH. Berlin: S. Karger. 1925. Pp. 92. M.6.

THE subject of this little volume is a synthetic and analytic study of cases of psychosis characterised by restlessness, inability to keep still, motor agitation, and hyperkinesis generally. A distinction is drawn between hyperkinesis in the sense of the neurologist—viz., chorea, athetosis, tremor, tic-like movements, and so forth, and the much more general character of the "psychomotility" of the author's psychotic cases. He alludes to the types of movement seen recently with some frequency after attacks of epidemic encephalitis, but concludes that in respect of them also a distinction should be made from the "pseudo-spontaneous" movements of his patients, which are more closely allied to those of some mental defectives—dancing and rotatory movements, pacing up and down, and so on. The essential difference resides in the fact of the hyperkinesis being accompanied by unmistakable psychotic signs, such as amnesia, mental confusion, hallucinations, and being therefore psychogenic in origin. Out of a large series of cases two main groups are separated: (1) those in which hyperkinesis was the major symptom and in which only one attack occurred; (2) those in which recurring attacks took place. Ætiological evidence is adduced associating the phenomena in many instances with infections. The author concludes that the hyperkinetic psychosis, so to call it, occupies a position midway between the exogenous and the endogenous psychoses; however this may be, he has clearly made out a case for the further study of this interesting clinical type on the basis of the peculiar character of its intrinsic features.

AMERICAN ILLUSTRATED MEDICAL DICTIONARY.

Thirteenth edition. By W. A. NEWMAN DORLAND. London and Philadelphia: W. B. Saunders Company. 1925. Pp. 1344. 37*s.* 6*d.*

THE preface to this revised and enlarged edition of Dr. Dorland's admirable dictionary states that since the last edition appeared there has been no "let-up" in the appearance of new terms in medical literature. Some 2500 new words have been added, several hundred of them from the terminology of dentistry, which seems to be going apace. Certainly, no medical word in current use, however new, seems to be missing from the dictionary, and the few omissions, which we have noticed in previous editions, have been made good. We are especially glad that the great scientific repute now associated with the name of Banting has at last led the compiler to admit that the Banting of the anti-fat diet was an undertaker (the word used is "coffin-maker") and not a physician. Pseudo-coxalgia is now included with a cross-reference to its various synonyms. Curiously enough, the confusion in regard to the several bearers of the name Schwartz(e) and their operations remains unresolved. Perhaps the word "stent" of the new prosthetic surgery might deserve admission. Stent was, we believe, an American dentist who invented a plastic material for taking impressions, a resinous compound which sets very hard; the word is now used to mean the impression itself, and in plastic work denotes a little mould used to hold a graft in place. In spite of the vast area of knowledge covered—there must now be more than 50,000 definitions and 120 tables—the dictionary remains of moderate size and pleasant to handle. In this its latest form "Dorland" will retain its old friends and find many new friends.

NEUROLOGICAL STUDIES.

Études neurologiques. Deuxième série. By GEORGES GUILLAIN, Professor of Clinical Neurology in the Paris Faculty of Medicine. Paris: Masson et Cie. 1925. Pp. 360. Fr.26.

WHEN the first series of these studies appeared in 1922 it was favourably reviewed in our columns, and general comment was then made on the advantages of the clinico-pathological method as practised by the French school with conspicuously good results ever since the days of Charcot. Prof. Guillain follows worthily in the succession of Maîtres whose labours combined to raise the repute of the Parisian school of neurology to its present high level. In this volume he pursues the same method of precise clinical examination correlated with equally careful pathological research. Among his papers herein collected are many of which the neurologist has already taken note; 40 in all, they range over the whole field, and include the description and study of the phenomena of a new reflex, the medio-pubic reflex; a case of callosal tumour (splenium) of an unusual kind; a series of communications on disseminated sclerosis and on Parkinsonian cases; and numerous others too varied to specify in detail.

While some are quite brief they are none the less informative; the majority date between 1922 and the present year, though a few belong to an older period. We hope that Prof. Guillain will continue to furnish the neurological world with similar essays, in which the graceful style of the author is used to impart valuable information of abiding interest.

JOURNALS.

BRITISH JOURNAL OF SURGERY.—The October issue opens with Sir D'Arcy Power's eighteenth Eponym on Thomas Bryant's ilio-femoral triangle and its diagnostic value.—R. Lawford Knaggs, in a series of able Hunterian lectures, has added very considerably to our knowledge of those bone diseases grouped around osteitis fibrosa. This issue contains his lecture on osteitis deformans, and having described its clinical picture and its histology he shows how close is the relationship between Paget's disease, osteitis fibrosa, and osteomalacia. —E. Rock Carling and J. A. Braxton Hicks contribute a paper on two cases of cyst-adenoma of the pancreas, one an operation case and the other found post mortem.—H. P. Winsbury White discusses the pathology of hydronephrosis, particularly of the pelvic type, and suggests that most of these cases have an underlying inflammatory cause.—F. G. Bell completes his survey of the pathology of the tumours of the testicle with a description of the carcinoma group.—Lymphaticostomy in cases of bad peritonitis is the subject of two papers by C. Hamilton Whiteford and Arthur Cooke. Though short, each paper makes it clear that this method of treatment is by no means satisfactory, nor is it clear that the original experiments in dogs on which it is founded can be proved correct.—The longest and by far the most important contribution is a Consideration of the Hypophysial Adenomata, by N. M. Dott and Percival Bailey, with an introductory note by Harvey Cushing. Their work is based on 162 cases of these tumours and is a brilliant example of the value of correlation of the clinical and histological findings. They give an exact description of the different types of tumour—the chromaphil and chromophobe adenomata and the mixed ones. It is found that the chromaphil group give acromegaly, while the chromaphobe produce hypopituitarism, and the mixed type show a mixed clinical syndrome. The authors have put the treatment on a rational basis for the first time.—F. R. Brown reports a case of a right duodenal hernia successfully operated on, thus giving the fourth recorded recovery.—B. C. Maybury and S. C. Dyke record two cases of urinary papillomata which spread by implantation, one in a hydronephrosis which resulted from the primary operation, and the other in three separate places in the abdominal wall after a suprapubic cystostomy.—The following rare or obscure cases are reported: 1. A Strangulated Femoral Hernia in Association with an Appendix Abscess in a Hernial Sac, by Norman Hodgson. 2. Two Cases of Hernia Through the Transverse Mesocolon, by F. S. Heaney and G. C. E. Simpson. 3. An Unusually Large Tumour of the Breast, by W. E. Tanner.—Section 2 of the Pathological Atlas contains further examples of the malignant diseases of bone, and begins the benign series with the chondromata.

A Liverpool surgeon writes to point out that Mr. F. T. Paul's "Selected Papers" were published not by "the surgeons to Liverpool Royal Infirmary," but by "the surgeons of Liverpool." The list of subscribers includes the name of every surgeon and assistant surgeon of the Liverpool voluntary hospitals.

PROCEEDINGS OF THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.*

(*Continued from p. 987.*)

Provision of Extended Medical and Allied Services.

(App. CIII. and Q. 23830–24024.)

Mr. L. G. Brock, C.B., and Dr. Smith Whitaker, on behalf of the department of the Ministry of Health concerned with the administration of medical benefit, attended before the Commission to answer questions arising out of the evidence of various witnesses. They presented a memorandum of discussions on certain of these questions which took place at five conferences convened by the National Health Insurance Commissioners in 1919. These conferences were held not only with the recognised representatives of insurance practitioners, but with various consultants and specialists, some of whom were nominated by the Joint Committee of the Royal College of Physicians, London, and the Royal College of Surgeons of England, and the Society of Medical Officers of Health, which had been conferring with the Government as to the working of the Ministry of Health Bill.

Grants had been voted by Parliament in 1914 for extra services in connexion with the insurance medical service and included provision for a service of medical experts, general practitioner clinics, laboratory services, &c. These grants were suspended owing to the war, and the conferences of 1919 were convened partly in view of the possibility of the revival of such provisions and partly because of the prospective early constitution of a Ministry of Health.

In the memorandum the question was examined of the possibility of some provision under the control of a public authority of the services under the following heads: (1) expert "out-patient" medical services; (2) ancillary services of skilled persons not medically qualified—e.g., nurses and masseurs; (3) general practitioner clinics; (4) referees and supervisory medical officers; (5) laboratory facilities; (6) treatment in residential institutions (as in-patients).

Under the first head questions of the necessary limitations both as to the range of service and the persons to whom it should apply were examined and also the nature of the checks which would have to be imposed to prevent excessive demands. It was recognised that the medical personnel of such a service would have to be selected and that remuneration would have to be on a time basis. The chief purposes for which general practitioner clinics might be set up were indicated to include joint surgery accommodation, facilities for second opinions and for special study, and also subsidiary centres at which treatment might be given by specialists attached to the clinics.

---

* References to the paragraphs in the printed statements issued as appendices to the reports of the oral evidence are given thus: "App. X. 69," and references to the oral evidence thus—Q. 1369.

The object of the discussions having been expressly stated to be the free exploration of the important subjects discussed and not the formulation of or agreement upon any definite proposals, no definite recommendations emerge, but it may fairly be inferred that those taking part in the conferences were satisfied as to the practicability (if financial considerations permitted) of setting up public services of the kinds referred to.

Specialist and Consultant Services.

Mr. Brock was asked whether an extension of medical services, as urged by witnesses, to include a specialist and consultant service was desirable, if the necessary funds were forthcoming, and, if so, how such a service could best be provided. He said that there were several reasons which made some extension very desirable if funds were available. The out-patient departments of the hospitals did not cover the ground; there was not sufficiently close touch between the general practitioner and the hospital specialist; and thirdly, such a service would have a valuable educative effect on the general practitioner.

As to the method, it was thought that the service would best be secured by the provision of consultant centres at which specialists in different subjects would attend, payment being made on the basis of so much per session. Such a system would also allow of arrangements being made to provide at those centres ancillary services such as treatment, massage, electrical treatment, and radiography. Where the patient was well enough to travel to the centre it would ordinarily be much more economical to pay for his conveyance than to pay for the conveyance of the doctor. Where a domiciliary visit was asked for, probably in the great majority of cases all that would be required would be a visit by an experienced general practitioner, the type of doctor who would normally be called in by his colleagues in the locality in any case of difficulty.

A rough estimate of the cost of this service was 2*s.* a head of the insured population, to include provision for domiciliary attendance, or about £1,250,000 for England and Wales, including about £100,000 for laboratory services for aids in diagnosis. It was not thought that a system based on contracts with the hospitals would work satisfactorily, but it would be very desirable to utilise hospital premises by renting them wherever possible. The utmost importance was attached to communication between the general practitioner and the consultant.

Treatment of Dependants.

Mr. Brock said that if a complete medical service, short of institutional treatment, were going to be provided for insured people, it must emphasise the anomaly that at present their wives and dependants can only obtain such medical treatment as they are able to pay for. It seemed, however, open to question whether an insurance system which left a good many sections of the population out of account was the best way to provide for the case.

> If it was proposed to provide either a general practitioner service or a complete medical service for the whole industrial population, there are strong arguments in favour of providing this service out of local funds and making it available to all sections of the population who desire to take advantage of it. . . . If such an extension of State or municipal medical service is contemplated, then the whole basis of payment and the method of organisation of that service would require to be reviewed.

The contingency appeared, however, too remote to call for any detailed examination.

An Income Limit for Manual Workers.

With regard to the British Medical Association's proposal that a limit of income should apply to manual workers, the witness pointed out that insurance at the present time depends not on total income, but on rate of remuneration; the distinction was very important, because the rate of remuneration is something which is ascertainable now, but total income is something which is only ascertainable in arrear. He said that to apply an income limit to manual workers the majority of whom are necessarily subject to the risk of unemployment, would in the Ministry's view be a quite unworkable scheme.

Hospital Provision.

Mr. Brock said that if out-patient departments were, in fact, providing, except in emergency, for cases falling within the competence of the insurance practitioner, they had only themselves to blame.

> But there is ground for believing that indirectly the Insurance Acts have increased the demand on the hospitals, because the institution of a general practitioner service has, I think, to a large extent broken down the old dread of entering a hospital, and has led to a demand for operative treatment at a much earlier stage than used formerly to be the case.

In the view of the Ministry it would not be desirable to attempt to include institutional treatment in the Acts as a statutory benefit. To provide the whole cost of in-patient treatment of insured persons would be extremely costly, and there is the difficulty that a statutory benefit implies some guarantee that the required accommodation will be available when it is needed.

> Any scheme which resulted in preference being given to a particular class, however large that class might be, must in our view be prejudicial to the voluntary system. The voluntary hospital appeals to everybody at present, because at present in theory it is available to everybody.

With regard to the pressure on the bed accommodation Mr. Brock said:—

> The amount of avoidable suffering and of unnecessary claims on the sickness benefit funds, of course, cannot be calculated, but it is safe to say that in the aggregate it is very considerable, and a more effective use of the bed accommodation already existing in Poor-law hospitals is urgently needed both as a matter of economy and even more as a matter of humanity.

It would, however, certainly not be safe to say that this would make up the deficiency in the provision of beds, partly because the vacant Poor-law beds are not always in the area where the demand is greatest.

As to the standard of equipment in the Poor-law infirmaries, Dr. Smith Whitaker said:—

> I am immediately responsible for the work of the medical officers who inspect the Poor-law infirmaries, and while I have not gone into the matter closely, I certainly have not gathered from their reports that there is such a low standard of equipment of Poor-law institutions, taking them generally.

(To be continued.)

DONATIONS AND BEQUESTS.—Mrs. Martha Sarah Gatfield, Ross, Herefordshire, who left £6808, bequeathed one-fifth thereof to the Hereford Hospital and the London Hospital.—The Manchester Public Health Committee have adopted a recommendation to contribute £1000 for the work of cancer research in the city.—Mr. Henry George Hill, Bristol, ironmaster, who left £293,893, bequeathed £1000 to the Bristol Royal Infirmary, and £500 each to the Bristol General Hospital and the British Benevolent Institution.—Mr. Robert, Killaloo, Londonderry, besides other bequests, left £1000 to the Londonderry Borough Infirmary. After other bequests he left the residue of his estate as to one-third to the Londonderry County Infirmary and one-third to such charitable institutions as the trustees of his will may determine.—The trustees of the late Colonel John Barlow, of Bury, have given £4000 to Preston Infirmary, especially for the accident ward, in view of the fact that the institution is called upon to take into account cases from a much wider area than that from which it draws its funds.—During the past month the Royal Manchester Children's Hospital has received a legacy of £1500 from the late Mr. William Henry Armitage, and £341 from Queen Alexandra flower festival.—Mr. Joseph Harriman, Leicester, left £500 to the Loughborough and District General Hospital and Dispensary, and £500 upon trust for the poor and infirm people of the parish of Shepshed.—Mr. James Chapman, manufacturer, Sheffield, who left £40,146, directed that, after certain bequests, the residue of his property be given as to two-eighths each to the Sheffield Royal Infirmary, the Sheffield Royal Hospital, the Jessop Hospital for Women, and one-eighth each to the Sheffield Free Hospital for Sick Children and the Blind School, Manchester-road.

THE LANCET.

LONDON: SATURDAY, NOVEMBER 28, 1925.

THE DEATH OF QUEEN ALEXANDRA.

The death of the Queen-Mother at Sandringham House on Nov. 20th has left its impression in every home in the country, for the Danish Princess who came to England 62 years ago to wed the Prince of Wales had identified herself more than any royal person had done before with the life of the common people. Owing to the spread of wireless equipment her progress was followed from hour to hour by a populace for whom she had become the embodiment of beauty and gracious service, and the wireless announcement of her death produced a spontaneous outburst of sympathy for the King and the Royal Family.

Sympathy for others was an outstanding feature of Queen Alexandra's nature, and these personal experiences did much to divert her genuine philanthropy into practical service. Her determined and unflagging efforts to alleviate and prevent misery continued throughout her long life, and the names and records of countless institutions commemorate the share she took in the work for which the nation constantly thanks the Royal Family. Her contribution to the efficiency of military nursing was in itself notable. At the beginning of the South African War the astonishing influence of Florence Nightingale had not yet borne its full fruit, and the War Office did not provide anything approaching a suitable equipment of nurses for the front. Had it not been for the voluntary work of civilians the conditions in South Africa would have been even worse than they were, and in this work the Princess of Wales took an important part. Realising that unreadiness was causing much preventable suffering and endangering lives which should be saved, she was beforehand with the War Office and insisted upon a substantial contingent of nurses being sent out from London hospitals to South Africa. Not only was the nursing of the wounded during the campaign placed on a more satisfactory basis, but both the country and the Army were awakened to the need for reform and better organisation.

The war was no sooner over than Queen Alexandra's Imperial Military Nursing Service was established to provide primarily for the nursing of sick soldiers in time of peace and, also, to form the basis of a larger organisation in time of war. To this was added a reserve service as the first means of expansion in the hour of need. Later there was set up Queen Alexandra's Army Nursing Board to which is committed the oversight of the entire military nursing service, and in 1921 Queen Alexandra's Military Families' Nursing Service was started to look after the welfare of the wives and children of Service men. Similar Queen Alexandra Nursing Services were established for the Navy and for India, and immediate descendants of these organisations are the Nursing Services which have been created for the Air Force and the Territorial Army. In all of them the Queen-Mother took the keenest personal interest, and she had an active part in the details of their establishment. But these are not the only positive achievements in the realm of nursing that the country owes to the eager alertness of a mind at once profoundly benevolent and essentially practical. It was at Queen Alexandra's instance that the Finsen light was brought from her native land to the London Hospital. She gave the hospital the first lamps and so was the means of introducing into England that cure of lupus by light which might otherwise have tarried. Her work for the London Hospital, of which she was President for the last 21 years of her life, was both public and private. To the full she used the healing touch that Royalty still possesses. She would go to Whitechapel at very short notice, and delighted to walk through the wards and chat with the patients, her face irradiated by sympathy and by the friendly smile which meant much to those whose share of pity and sympathy had often been small. To the nurses she was an equally welcome visitor. She realised the nature of their trials and fatigues, and it was often said that she would herself have made an excellent nurse. The number of hospitals, nursing and charitable institutions in which Queen Alexandra took a more or less direct interest was great, and it is not surprising that her name should have been attached to curative institutions in such widely sundered lands as Canada and Burma. "Alexandra Day" is certain to keep her name fresh in the hearts of future generations who will erect the worthiest memorial to her, and that which she would best have appreciated, by continuing and enlarging the help to hospitals and other charities which flows from this annual expression of England's affection and reverence for the best beloved of all her adopted daughters.

◆

A NEW JOURNAL OF EUGENICS.

It is now more than 30 years since the appearance of the first of the series of memoirs in which Prof. Karl Pearson has proved what valuable service the mathematician can perform in the general field of biology. At the beginning of this period, such researches—sufficient to occupy the whole time and establish the reputation of most men—were the parergon of a teacher and active investigator of applied mathematics, but, for the past 16 years, as first Galton Professor of National Eugenics, Prof. Pearson has devoted the whole of his energies to the invention and application of exact quantitative methods to the study of biological problems, above all of the problems of human biology. Much of the gigantic output of himself and his pupils has, naturally and rightly, been methodological; the equipment of a factory must come first. Many of these methods have been invaluable to workers outside the biological field, but they were devised for biological ends, and in no year has the Galton Laboratory failed to produce results as well as methods.

The tools of this intellectual factory are now so numerous and so sharp that its manager feels justified in making new provision for the distribution of output. The *Annals of Eugenics*, the first two parts of which have recently appeared,[1] will be devoted wholly to the scientific treatment of racial problems in man; bibliographical matter will be reduced to a minimum, no other topics than the problems of race in man will be dealt with, and the papers published will be the work of trained scientists. It is to be expected that a majority of the papers will be statistical, but that good papers which are not

"mathematical" will not be excluded is shown by the inclusion in the first issue of an interesting pedigree of Epicanthus and Ptosis, the work of Dr. C. H. Usher. Mr. Anthony Hill contributes a study of the movements of the birth- and death-rates in England and Wales since 1838, and in Sweden since 1749, which shows that the inter-connexion of these rates is a much more difficult thing to interpret than some enthusiastic neo-Malthusians would have us believe. In fact, he says, "taken as a whole the evidence is that, apart from the secular trend, there has been but slight connexion in either country between the death-rates and the birth-rates closely following them, over the period of time for which the statistics are available." The bulk of the number is devoted to two memoirs (each to be continued), one by Prof. Pearson and Miss Margaret Moul on the Problem of Alien Immigration into Great Britain, illustrated by an examination of Russian and Polish Jewish children, the other by Miss Ethel M. Elderton on the Relative Value of the Factors which Influence Infant Welfare, based upon data provided by the medical officers of health for Rochdale, Bradford, Blackburn, Preston and Salford. In the former memoir the question is posed whether it is expedient to permit unrestricted immigration of aliens into this crowded land unless they possess some racially desirable character to a degree above the average of our own population. A thorough investigation of school-children leads to the conclusion that Jewish immigrants from Eastern Europe do not fulfil the postulated condition. Miss Elderton's equally careful study of the medical officers' data leads to the conclusion that purely environmental factors are, as a whole, far less influential upon infant welfare than factors which are presumably inborn. These two memoirs are, we think, of a high order of merit, indeed worthy of their authors' scientific reputation; as high praise as can be accorded to any contribution to statistical science. Nobody who has not worked through such papers with a calculating machine beside him is competent to offer detailed criticism.

In their article on the Immigrants Prof. Pearson and Miss Moul have correlated a large number of pathological or quasi-pathological characters (condition of cervical glands, tonsils, ears, signs of tuberculosis, heart trouble, defective teeth) with intelligence. Most of the coefficients are insignificant and, they say, "to sum up we have not succeeded in finding any relation of real prognostic value between intelligence and such pathological characters as we have been able to measure." Robust anti-eugenists may regard this as an admission that Nature does not improve the racial average of intelligence when she uses tuberculosis, for example, as a means of selection, or alternatively that "intelligence" is not of racially important survival value. Perhaps the truth is that we have not such exact knowledge of the after-fates of school-children with pathological stigmata as we usually suppose. Continuous health records telling us what happens after the children leave school are a crying need. Perhaps the time will come when Prof. Pearson and Miss Moul can treat in the same detail school and adolescent populations. We conclude with one tiny caveat to Miss Elderton. Although, like all scientific statisticians, she warns us against assuming that causation and correlation are identical, she does sometimes use language that implies that correlation between cleanliness of home depends upon health of mother. "In Blackburn the delicate mother seems able to keep her home clean." May not "dirty homes" sometimes have meant conditions beyond the power of the most robust housewife to remedy? The dirty home may have been the antecedent rather than the consequent term. Dr. W. McC. Wanklyn's remark may be recalled: "Persons so placed may make some effort, and wear out body and soul in the process, or they may just sit down, as it were, and give it up; the task is too hopeless, too impossible for any human being. They lose heart, they lose hope, they lose self-respect. It is an oft-told tale, but none the less true. They become bankrupt both in money and in self-respect. That is one of the principal causes of the insanitary conditions found in houses let in lodgings." We are not quite sure that the argument of p. 143 really surmounts the difficulty.

We wish the new journal that prosperity which the merit of its first numbers should ensure and heartily congratulate the editors on its form and contents.

HEALTHY GERM CARRIERS: LIBERTY AND THE LAW.

A grave problem of public health administration is raised by incidents like the recent outbreak of typhoid fever at Streatham, where 27 persons were infected by a woman milk-seller who, though herself healthy, was an unconscious germ-carrier. "We have no power to keep her in permanent isolation," said Dr. F. G. Caley, the Wandsworth medical officer of health; "she is actually a person in good health. All we can do is to prevent her going back to the milk business and handling any kind of food for sale." Even greater difficulty is suggested by a recently reported American case,[1] where a sailor on board a fishing schooner appears to have been the unconscious cause of six cases of typhoid fever amongst the crew. The man was not a food-handler at all. What powers would a medical officer in England have in such a case?

There are powers in our public health legislation for ensuring the notification of certain diseases and for preventing the spread of infection. There are well-known sections devoted to the limited purpose of protecting food-supply by restraining the employment of persons likely to spread infection. Local Acts often contain provisions which go still further, and sometimes compensation may be awarded to persons who, as sources of infection, are induced to give up their trade.[2] Specific references to the "carrier" are rare as yet in the general legislation of the country. Articles XIII. and XV. of the Public Health (Pneumonia, Malaria, Dysentery, &c.) Regulations of 1919 give certain powers to medical officers of health who suspect that anybody employed in preparing or handling food or drink for human consumption is "a carrier of dysentery infection" or "a carrier of enteric fever infection." They may notify the manager of the business that it is necessary to examine the suspected person, and the Regulations enjoin that everybody concerned is to give the medical officer all reasonable assistance. If the medical officer thus discovers a carrier of dysentery or enteric fever he may notify the carrier's manager and the carrier himself with a view to preventing his further employment in that business for a specified period. On receipt of such notice the person addressed must comply with its terms. These Regulations give the usual general powers for securing the treatment of fever cases in suitable hospitals, but there is nothing specific as to the isolation and treatment of the healthy carrier, nor do the Regulations apply to any carriers except those engaged in preparing or handling food or drink.

---

[1] Public Health Reports, vol. xl., No. 42 (Oct. 16th, 1925).

[2] See, for example, S. 102 of the Wakefield Corporation Act of 1924.

Similar provision was made for Scotland in 1919, but two years later (as we noted at the time[3]) the Scottish Board of Health took a definite step in advance of England. It cancelled its provisions as to dysentery and enteric fever carriers and issued the Public Health (Infectious Disease Carriers) Regulations (Scotland) of 1921. These defined a "carrier" in relation to a particular infectious disease to mean "a person who has within himself the germs or other infective virus of that infective disease, but has no other sign or symptom thereof, and is certified to be a danger to others in terms of these Regulations." To make a man a carrier for this purpose in Scotland he must first be certified by a medical officer of health and one other doctor as dangerous by reason of the probability of his spreading infection. Certification is for three months, with power to re-certify on re-examination. On the carrier's side a fresh examination may be demanded at any time on giving notice to the medical officer, and there is a right of appeal to the Board. The important point is that, so long as anyone is a carrier of an infectious disease, the Scottish Public Health Act and the Regulations made thereunder apply to him as they apply to a person actually suffering from that disease. The effect is that, by the application, for example, of Sections 54–56 of the Scottish Act, if the carrier is without proper lodging or is so lodged that proper precautions cannot be taken against spreading infection, he can be removed to hospital and detained there; moreover, he incurs a penalty—though the maximum (£5) is trifling in comparison with the cost of an epidemic —if he wilfully exposes himself without proper precautions. The Scottish Regulations, however, stop short of compelling the carrier to undergo prescribed treatment. We must look overseas for a stronger lead. New South Wales, under her Public Health (Amendment) Act of 1921, made Regulations in 1922 which begin with a similar definition. "A carrier shall be any person having in his nose or throat, or in his excretions or discharges, germs of any infectious disease, although presenting no signs or symptoms of the disease." They provide for authenticating the presence of disease germs by bacteriological tests, and for compulsory medical examination of the carrier by a medical officer of health or authorised medical practitioner. They enact that carriers may be placed under medical surveillance, or isolated and detained if necessary to prevent the spread of infection. Anyone who has been formally notified that he is a carrier is forbidden to take part in the preparation, handling, or serving of food or drugs, or the handling of vessels or receptacles used for that purpose. Moreover, the carrier must obey such instructions as a medical officer of health or an authorised practitioner may specify, for such period as is directed. This last provision is indispensable. To know that a carrier has been tracked down in a district and that an eye must be kept upon his activities is something, but it is not enough. There should be power to isolate and treat him just as much as if he were an actual sufferer from the disease which he is liable to disseminate. The individual must put up with inconvenience in order that the many may not suffer through him.

There seems no reason why the Ministry of Health might not legislate along these lines by regulations issued under its existing statutory powers. Section 130 of the Public Health Act of 1875, which corresponds to Section 78 of the Scottish Act of 1897, is surely wide enough. But do we know the extent of the problem? Are carriers of fever infections in England to-day to be numbered in tens or in hundreds or in thousands? And, if special institutions are provided for their isolation and treatment, will there not be obstinate cases in which prolonged detention will have all the appearance of imprisonment for life? If this be so, the law courts will probably be inclined to say that the liberty of an outwardly healthy and morally blameless person is not to be taken away by mere departmental ukase, but that if Parliament intends the healthy carrier to be incarcerated Parliament must say so. Until there is something specific upon the statute-book judges can hardly be blamed for thinking more of habeas corpus than of *Bacillus typhosus*. Meanwhile, if it is true that healthy carriers cannot legally be segregated against their will, still less can they be subjected to compulsory surgical operation. It may be reasonably proved that operations (tonsillectomy, for example, in cases of diphtheria carriers or removal of the gall-bladder in cases of typhoid carriers) offer a fair prospect of cure. Even if it were enacted that healthy carriers must submit themselves to prescribed treatment, the question of surgical operations would require careful handling. It might strike the public mind as too suggestive of those advanced American States which (on paper, at any rate) adopt the eugenic principle of sterilising their degenerates. With the recent Streatham case fresh in its memory, this country might be willing to empower the detention of the healthy carrier till such time as he can be certified as innocuous, all medical and surgical facilities being offered him in order to expedite his cure and release. Some years ago several American States passed a measure for compulsory notification, examination, quarantine, and treatment (backed by fine, imprisonment, and liability in damages) in respect of venereal disease. This country has not shown itself ready to follow suit. One of those States (Iowa), as an alternative to quarantine, allowed the patient's release on bond of 1000 dollars on condition that he would not expose anyone to infection, would continue his treatment till cured, and would observe all rules and regulations prescribed. It was an interesting experiment, but in this country we shall do more by appealing to the good sense of our countrymen who have the misfortune to be germ-carriers than by exacting money bonds from them.

◆

PUBLIC HEALTH ADMINISTRATION.

SHOULD the Rating and Valuation Bill now before Parliament become law, the Ministry of Health has stated its intention of reviewing the question of percentage grants to local authorities for health services. The new proposal, outlined in a letter addressed by the Minister to municipal authorities, is to devise a scheme by which a fixed grant covering a period of years is made to the local authority, to be expended upon whatever health work the authority chooses, provided that a recognised standard of efficiency is maintained. The same letter intimates the Government's intention to make one local authority responsible for the finance of each sanitary area; as it is, municipal finance may at any moment be upset by the activities of boards of guardians over which the council has no control. Expression is also given in the letter to the Government's conviction that if the total health and hospital provision in any area is to be effectively and economically worked, it must be handled as a whole by a single health authority. The Government scheme therefore proposes to institute a single set of local authorities in the various areas of local government with provision for coördinated action. These proposals bring one stage nearer the reform of the Poor-law in the sense of the Minority Report of the 1905–09 Commission.

ROYAL DENTAL HOSPITAL OF LONDON, SCHOOL OF DENTAL SURGERY.—The annual clinical "at home" was held at the Royal Dental Hospital on Nov. 21st, when about 80 patients attended. There were shown various conditions of clinical and scientific interest, including pathological conditions of the jaws, teeth, and associated parts; cases illustrating the relation of dental to general disease, cases of orthodontic interest and prosthetic cases. Mr. F. St. J. Steadman gave a very successful demonstration of regional anæsthesia and there was also a display of specimens, models, and X ray photographs. About 250 visitors were present.

"Ne quid nimis."

EXPERIMENTAL CANCER RESEARCH.

IN the twenty-third annual report of the Imperial Cancer Research Fund which we notice on another page, Dr. J. A. Murray, F.R.S., the director, refers to the publication in THE LANCET of July 18th, 1925, of the paper by Dr. W. E. Gye as the outstanding event of the year. He summarises Dr. Gye's conception of the ætiology of cancer in the following terms:—

> "The essence of Dr. Gye's conception is that malignant growth results from the concurrence of two factors—an ultra-microscopic microbe and an unstable chemical factor derived in his experiments from propagated malignant tumours of animals, and it would be erroneous to regard either of these factors, singly, as the cause of cancer. The direct evidence of this dual origin of new growths has so far only been furnished for the Rous fowl sarcoma and for a transplantable sarcoma of the mouse. For other tumours the evidence is indirect, cultures of these supplying the ultra-microscopic microbe, the specific unstable chemical factor being supplied by an extract from the Rous fowl sarcoma, in which species of animal the two injected simultaneously gave rise to progressively growing sarcoma. Injected singly, they are inert. The delicate racial and tissue specificity governing the transmission of malignant new growths therefore attaches to the labile chemical factor, and not to the microbe. One of the gravest objections to previous forms of the parasitic hypothesis of cancer is thereby met. These experiments have only been possible by the use of the propagated animal tumours which are sufficiently exempt from ordinary bacterial contamination, and it is a legitimate source of satisfaction to this Fund that their prevision in maintaining this material over many years, including the war period, should have received its due acknowledgment and reward.
>
> "It is obvious that this dual conception of the ætiology and pathology of cancer, should it be confirmed, introduces a new orientation in every aspect of the cancer problem: statistics, epidemiology, causation, prevention, and treatment."

Dr. Murray states that the workers of the Fund have, at Dr. Gye's request, undertaken a critical repetition of his fundamental experiment, and he deprecates premature speculation and anticipation in view of the fact that the new problems are susceptible of direct experimental study. But we may perhaps be allowed to express the opinion that everybody interested in the cancer problem—and there are many—will look forward to the next annual report of the Fund with the keenest interest.

Of the work published during the past year two papers are specially referred to by Dr. Murray. It is now recognised that cancer of the skin can be produced at will in mice by repeated painting of a localised area of the skin with tar. If this is repeated over many months several times weekly about 70 per cent. to 80 per cent. of the animals will after five to nine months develop a typical skin carcinoma. Dr. Findlay has found that even the single application of hot tar may, in exceptional cases, produce cancer after a long period of time—about a year. The tar no doubt remained in the traumatised area for a prolonged period of time. But from the clinical point of view it is interesting to have an experimental demonstration that a trauma due to a single extraneous intervention may be responsible for the genesis of cancer. The second investigation referred to deals with the theory which has been propounded that cancer is due to a loss of nervous control over a group of cells. Malignant new growths are not efficiently innervated, if indeed they contain any nerves at all. The cells of the normal skin, on the other hand, are supplied with a very rich network of fine nerve-fibres. It has been suggested, therefore, that the origin of cancer is to be found in this difference; in other words, that normal cells become cancerous or, at least, predisposed to cancer when they escape for some reason or other from nervous control. This view was submitted to an experimental test by Dr. W. Cramer, who denervated an area of skin and then submitted it to chronic irritation by tar-painting. It was found that the denervated area responded to tar-painting by the production of tumours not more rapidly but much more slowly. It is clear, therefore, that absence of nervous control does not predispose to cancer. On the contrary, it seems to retard the genesis of cancer. It would appear from these observations that in the production of a tar tumour we are dealing with the effect of a chronic irritant not on the epithelial cells only but on the tissue as a whole. Owing to the fact that these experiments necessarily extended over many months and that during that time a gradual nerve regeneration took place in the denervated area it was not possible to determine whether a permanent absence of nerve control would completely inhibit the genesis of cancer. These results would appear to be in keeping with the regression or limitation of the growth of a cancer which has sometimes been obtained in man by denervation.

To the superficial observer it may seem remarkable that the production of cancer by the laborious application of tar should still occupy the time of investigators while acknowledgment is made of the revolution in cancer research introduced by the work of Dr. Gye and Mr. Barnard. It is obvious, however, that any new knowledge must be harmonised with what is already known, and furnish a rational account of the way in which cancer arises from normal tissues, before it can be recognised as an adequate solution of the problem of the ætiology of malignant new growth.

GASTRO-ENTEROLOGY IN SPAIN.

THE subject of special clinics and hospitals for special diseases is being discussed with increasing frequency in medical circles in this country, and a point seems to have been reached when the advocates of so-called all-round knowledge have come to defend with increasing vigour those portions of the human body whose study has not yet been seized from them by otologists, neurologists, dermatologists, cardiologists, urologists, and other specialists. The outcome is yet to be seen, but it has already become somewhat remarkable that special departments for diseases of the endocrine organs, the alimentary tract, and metabolic diseases are not to be found in London. Opinion may differ as to whether this is desirable or not. Advocates of further specialisation will, however, be interested in a recent Spanish publication which we have just received.[1] The Madinaveitia Institute at Madrid was recently created for the closer study and appropriate teaching concerning gastro-enterology, endocrinology, and the disorders of nutrition. It comprises a large out-patient clinic and 12 wards, where upwards of 400 severe cases are treated in the course of each year. The X ray and laboratory equipment are of the latest pattern, and the yearly reports contain matter of high scientific interest. The article on the surgical treatment of gastric ulcer, by Dr. Urrutia, contains a learned survey of the present opinion of surgeons in all countries on this subject, and it is instructive to note the growing interest in the operation of gastrectomy, and the increasing suspicion as to the ultimate value of gastro-enterostomy prevalent in Spain. Dr. Carrasco Cadenas has contributed an article on the diagnosis and treatment of diabetic coma, and his insistence on the diagnostic value of estimation of the alveolar CO_2 tension is sufficient proof of the deep attention being given to the subject. Dr. Cadenas is emphatic concerning the necessity of giving large and repeated doses of insulin during coma, and shares the scepticism of other authorities concerning the value of bicarbonate administration. The laboratory examination of cases with deranged gastric, pancreatic, or hepatic function is conducted by Dr. H. G. Mogena, who contributes three excellent articles to the annals of the Institute. By a special technique, carried out with the aid of the X rays, this observer has been able to introduce duodenal sounds with rapidity and precision, and calls attention to the facility with which the duodenum can in this manner be filled with barium and useful pictures obtained in cases where ulceration is suspected. He has also been able in many cases to demonstrate hepatic insufficiency by the delay in appearance in the bile of tetrachlorphenolphthalein after intravenous administration of that dye. Altogether the first volume of the reports of the Institute will be received with deep interest in this and all other countries where the progress of medicine excites sympathy.

---

BIOLOGY OF POPULATION GROWTH.

IT is an interesting fact, coming within the experience of most scientific workers at one time or another, that a conclusion on any subject reached by apparently unassailable logic often turns out to be erroneous when detailed practical experimentation is substituted for theoretical exposition. The common jibe of "armchair critic" indicates that this experience is not infrequent in other departments of life. In this connexion the overwhelming logic of some of the arguments put forward by Malthus are no exception, and the obvious difficulties attendant upon controlled population experiments over a long period of time are probably sufficient reason why so much of what Malthus taught is accepted by many of his unquestioning followers at the present day. Prof. Raymond Pearl is not one of these; his painstaking and laborious investigations into some of the problems of applied biology are sufficiently well known to demand great respect, for his writings and his ingenious work with flies for carrying out population experiments in a laboratory to some extent get over the apparent difficulties of putting Malthusian doctrines to a scientific test. It was the "compelling logic" of the argument that the prophesied increase in human population would be bound to lead to an increase in the sum total of human misery and wretchedness that first aroused his suspicions, and in a new book[1] he has carried his previous work a step further by analysing in considerable detail the course of population among the indigenous tribes in Algeria over a period of 75 years of recorded census history. As a result of this and of other work already referred to on the fruit-fly, and further investigations in the experimental population of hens, he has reached certain important conclusions. He first shows "that populations grow in size according to the same mathematical law that individual animals and plants follow in the growth of their bodies in size." Further, "human populations grow according to the same law as do the experimental populations of the lower organisms," and the trends of the birth-rate and death-rate amongst the Algerian natives have been what would have been expected on certain mathematical considerations as expressed in the form of a logistic curve. The evidence necessary to establish these conclusions represents an enormous amount of labour, but Prof. Pearl and his collaborators have gone further and endeavoured to establish the biological causes influencing the shape of this curve. Evidence is brought forward to show that both for the lower organisms and for urban populations of human beings density of population will adversely affect the rate of reproduction. The economic factors of wealth by indirect psychological and social effects tend to express themselves in the sexual activity of human beings, and through sexual activity in birth-rates. With all this evidence and with the certain fact before him that "the human population of the world is going on increasing for a long time to come," Prof. Pearl is beginning to feel very uncertain as to the "inevitable misery doctrine" to which at one time he appears to have adhered. He now maintains that this doctrine overlooks certain important facts. In the first place, the great increase in population of recent years in various countries, and in the world as a whole, has not led to such a marked increase in squalor and wretchedness and general unhappiness as would have been expected. "Even allowing for the misery entailed by the great war," he writes, "it is surely true that at no previous time in the recorded history of mankind was so large a proportion of the population on the whole so happy, and so socially and humanely well off as they are right now." The reason for this is said to be, first, in the orderly evolution of human knowledge; applied biology is still in its infancy, and "one hears no note of pessimism from the chemists." Secondly, the adaptive potentiality of the human organism appears to be largely ignored, and yet it seems to be the crux of the whole matter. The new situations beginning to arise by the threat of over-population will be met by adaptation to environment. Birth control Prof. Pearl defines as "an intelligent adaptive response to an environmental force, population pressure." Public health and hygiene are further examples of these adaptive processes already at work. The comparative optimism of Prof. Pearl's conclusions is perhaps the most striking feature of his latest work, and both his work and his conclusions demand close attention.

LIPIODOL IN BRONCHO-PULMONARY DISEASE.

REFERENCE was made in THE LANCET last week to certain advances in the use of lipiodol in cerebral localisation. In the present issue Dr. Carlos Heuser, of Buenos Aires, describes his application of Sergent's method to the diagnosis of early pregnancy and to find out whether the Fallopian tubes are patent. But this is not all. Recent work in Canada indicates that in the diagnosis of broncho-pulmonary affections there is opening up an extended field for the use of this iodine-containing oil. Introduced first in France by Sergent and Cottenot for radiological investigation of bronchiectasis, and described first in this country by Armand-Delille and A. Moncrieff,[1] lipiodol has been increasingly used for the diagnosis of this particular disease, while a warning against its possible adverse influence on tuberculous lesions of the lungs has been uttered by the French workers. Dr. D. H. Ballon, however, in a recent paper,[2] points out that this theoretical objection, based upon the danger of pulmonary congestion from the iodine, has not been substantiated in his experience. Further, he maintains that the intratracheal route favoured by Armand-Delille and his co-workers, while perhaps justifiable in children, has no justification in the case of adults when a bronchoscope in skilled hands presents a much more satisfactory method. One part of a 20 per cent. solution of cocaine and two parts of 1 in 1000 adrenalin are used as a local anæsthetic for the pharynx and larynx, and bronchoscopy is performed on the radiographic couch. The instrument is passed beyond the vocal cords, and after further anæsthetising the operator injects about 30 c.cm. of warmed lipiodol through a long syringe. X ray pictures are then taken in various positions, the oil being moved by gravity to any particularly indicated part of the lungs. No discomfort appears to result from the lipiodol; the lung is remarkably tolerant, although there appear to be personal idiosyncrasies for the oil. No ill-effects have been noticed on tuberculous lesions, and lipiodol has been employed in certain cases described by Dr. E. Archibald in the same journal for determining the suitability of these patients for operative interference. Such surgical measures as thoracoplasty for the collapsing of cavities in the lungs are being undertaken more frequently, and the exact localisation of the extent and situation of such cavitation rendered possible by the use of lipiodol has an obviously important bearing on these procedures. In particular, in patients in whom such an operation as total posterior thoracoplasty has been performed, for example, two or three years previously, the new bone formation, irregularity of the chest wall, and thickening of the pleura render any subsequent ordinary radiogram of the thorax particularly obscure. If such a patient has a recrudescence of symptoms, as occurred in the three cases described by Dr. Archibald, accurate diagnosis is impossible without the use of lipiodol injection. This recent work is of importance in introducing a comparatively harmless method of injecting lipiodol and in establishing the fact that this oil is apparently non-irritant even to tuberculous lesions. The application of both these facts still further extends the use of this already useful substance.

ABDOMINAL LEVELS.

It is a commonplace of information, not only among surgeons and anatomists, but also among students, that the abdominal viscera are not always arranged within the cavity in absolute accordance with the simple plan that adorns all anatomical diagrams of the contents of the belly. We are not referring to the morphologically interesting examples of abnormal situation which are met with occasionally, but to what may be termed exaggerated lowness of levels with normal general arrangement. The transverse colon, placed in the pictures above the umbilicus, is more often found below—and well below—that point, and the stomach levels are no less striking in their variations. Anatomically, it would seem natural to give to these freely movable viscera a wide latitude in levels, associated with changes in the content of small intestine, and reserve narrow limits of "normality" for the colon on each side, where it is secondarily fixed to the dorsal wall. Among the interesting papers presented at the meeting of the Anatomical Society on Nov. 20th was one by Prof. R. J. Moody, who has been for some little time in this country. He had been able, by radiological methods, to estimate the position of the stomach, colon, and edge of the liver in 1000 students in California and, in demonstrating his results before the Society, showed how much these normal and healthy young people differed in respect to the positions of these viscera from what is usually accepted as the correct description. His material ranged in age from 16 to 25, male and female, and included athletes and gymnasts. None seemingly had any abdominal weakness or complaint. The average lowness of level of the organs mentioned, rather more marked among the women, would seem—even if all allowances are made for the conditions of X ray work on the one hand, and for those of the dissecting room subjects on the other—to call for the admission of much greater extent in range of level, and of possible lowness in individual level, than is generally conceded. The anatomists present appeared to have no objection to such conclusions. Radiologists have been instrumental in many ways in modifying some of the rigid conceptions held by the older school of formal anatomists, especially in the abdominal domain, but much more work and observation is required before the divergence of opinions in some cases can be reconciled. It is well that the formal anatomist should freely recognise the range of informality in the living body.

THE SURGEON IN BATTLE AT SEA.

In the *Military Surgeon* for October Rear-Admiral E. R. Stitt, the well-known Surgeon-General of the U.S. Navy, writes on the work of the naval surgeon in battle at sea. He opens with a story of the loblolly boy of the *Chesapeake* in her famous action. The loblolly boy was, in the British Service also, precursor of the sick-berth staff, loblolly being vernacular for the gruel he brought to the sick. After a glance at the medical preparations made by Augustus, as he became, at Actium, Admiral Stitt remarks that Hadrian's triremes (with a complement of 200 men) had each a surgeon, who received twice an ordinary officer's pay and hence went by the name of *duplicarius*. In the eleventh century barbers practised on board ship, and later Venice put surgeons and physicians in her galleys. In the wooden man-of-war the medical station was in a protected place below the water line. In those days British and Colonial ships-surgeons scalded their amputating knives, thinking by doing so to diminish the pain of the cut, and so anticipated Lister. In the Chinese-Japanese War the medical station was single, and it is on record that all the doctors and medical equipment of a ship were sometimes lost by a single shell explosion. Dressing stations were thereafter divided and put behind armour. The first "hospital for battle" was provided in the plans of the *Tsarevitch* in 1903. Admiral Stitt recounts the horrors of the defeat at Tsushima, when the ship *Askold* had one dressing station in the torpedo room, and two auxiliary stations, forward and aft, in charge of "feldshers," a word which recalls the "field shearer" or barber. Even at Jutland the ship's barber was among the ambulance party on *Seydlitz*. After reviewing reports of many recent naval engagements, Admiral Stitt concludes that two or more dressing stations must in future be available below the protective deck, and in the latest ships of the U.S. Navy a third is planned for the engine-room. Accessibility is difficult to attain now that ships are so much cut up into small sections as a protection against poison gas. For the same reason it must be possible to shut off the plenum ventilation without a moment's delay. A perfect stretcher for naval use is still wanting; Admiral Stitt mentions the Neil Robertson with approval, but in the future the wounded seaman may be removed on an ambulance aeroplane and the naval hospital ship come to resemble the aeroplane carrier. Every naval medical officer will be grateful to the Surgeon-General of the U.S. Navy, to whom we already are indebted for an admirable laboratory manual, for the picture he has given of life on shipboard in past times, and for his glimpse into the future.

NINETEENTH CENTURY SCIENTISTS.

Burns's well-known aspiration that we might see ourselves as others see us is one which workers in the field of natural science should bear in mind. There used to be a popular idea (it has nowadays almost disappeared) that science, as opposed to other fields of thought, was generous to fellow workers, was never dogmatic, did not know the meaning of heresy, and was ready to receive new ideas with open mind. This view of science was contrasted with the conventional views of religion, and the popularity of such "tenth rate" books (the epithet is Mr. Murray's) as Draper's Conflict between Religion and Science showed that this view had gained much ground. In the book [1] before us Mr. Murray, a parish priest, a widely read man, and by internal evidence a mathematician, pins out science in the nineteenth century on the dissecting table and sets out with cold precision the failings, the quarrels, the heresy hunts, and hidebound convictions of scientists to one another. His book is not pleasant reading, but, like many a bitter medicine, it should do good. The faults which Mr. Murray shows up so unsparingly may not be at present in evidence, but history shows that they are likely to recur. Sir Oliver Lodge, who has contributed an introduction to the book, gives the matter of it in a nutshell: "Surely the world of science is free from prejudice and is ever ready to welcome truth! So we try to think. But is it so? Does history bear this out?" Mr. Murray answers the question in the negative. He takes the lives and works of nineteenth century leaders in science—Jenner, Simpson, Lyell, Helmholz and Joule, Darwin and his predecessors, Pasteur and Lister, and a numerous band of others ("forgotten scientists" he calls them)—and shows how one and all met with bitter opposition or, still worse, with studied neglect from their fellows. Mr. Murray might have included in his list the John A. R. Newlands, who discovered and published papers on the Periodic Law, provisionally styled by him the Law of Octaves, some five years before Mendeléeff and Meyer, and whose work was received with derision. Occasionally one who had fought and conquered neglect or opposition to his own work (we forbear to cite instances), so far from profiting by discipline, proved just as bitter towards a new seer as any of his fellows. Mr. Murray's book is a store-house of information upon nineteenth century science; it is a work which should be read by everyone interested in human nature.

POLYCYTHÆMIA RUBRA AND X RAYS.

WE publish in this issue of THE LANCET an interesting and suggestive note by Dr. S. W. Patterson, physician to Ruthin Castle, North Wales. He gives a clinical record of a patient suffering from polycythæmia rubra, associated with high blood pressure and blotchy non-pruritic rashes. The treatment adopted consisted of a lacto-vegetarian diet, the administration of 1 gr. of thyroid twice a day, and intestinal douching twice a week. X ray treatment to the long bones was given twice weekly, on 25 days for eight minutes each, during a period from July 4th to Oct. 17th, diathermy being applied to the hands and feet on the other four days a week. The treatment seems to have been dramatically successful, the red cells being diminished from over 7,000,000 per c.mm. to normal, and the blood pressure from a systolic level of 204 mm. Hg and a diastolic of 120 to normal, the improvement being associated with a marked sense of well-being. Nine months after treatment the improvement has persisted, the blood count still being normal. The condition of polycythæmia rubra is an extremely interesting and somewhat obscure one. Since the year 1923 when Osler first clearly defined the condition, after its previous description by Vaquez, Cabot, and others, a great deal of attention has been paid to it, and it is probably somewhat more common than it was originally supposed to be. A routine examination of the blood in patients with florid appearance and high blood pressure would probably reveal more cases in an early stage. The association of high pressure with polycythæmia has long been familiar, and a form was described by Geisböck as polycythæmia hypertonica. There are two special points of interest about Dr. Patterson's case. First, the persistence of the good results of the X ray treatment, and secondly, the remarkably good effect of this treatment upon the raised blood pressure. The first of these may possibly be due to the fact that the case would appear to have been comparatively mild in degree with only just over 7,000,000 red cells per c.mm., and thus possibly was discovered in an early stage. The beneficial effects upon the blood pressure support the suggestion made by Dr. Patterson that this method of treatment is worth trial in cases with high blood pressure apart from this disease, especially those associated with some increase in the red cells and heightened viscosity of the blood.

ROYAL SOCIETY OF MEDICINE.

THE annual banquet of the Royal Society of Medicine, held at the Hotel Victoria, London, gave its President, Sir StClair Thomson, the opportunity to set out something of the great part played by the Royal Society of Medicine in the life of the community. He described the Society as a guild for the diffusion of knowledge in the science and art of medicine, the gold being dug in practice, in hospital wards, in laboratories and museums, as well as garnered from the progress of neighbouring sciences; but it was, he said, the function of the Society to test this gold, to mint it, and to put it into circulation. He spoke of the developments likely to take place under the management of the new whole-time secretary, Mr. Geoffrey R. Edwards, B.A., who had already made arrangements for keeping the library open during the long vacation, and for making it available on two evenings a week up till 10 P.M. It is, as the President remarked, not only the chief medical library of its kind in the Kingdom, but the most complete medical library in the Empire. But he also took the opportunity of acknowledging once again the signal services of the late secretary, Sir John MacAlister, whose 38 years of ungrudging and loyal service came to an end in April last. It was during this period that the removal took place of the old Medico-Chirurgical Society from "two or three stuffy rooms" in Berners-street to a building in Hanover-square, followed by the federation of this Society with 17 others into the Royal Society of Medicine. In the last session, as he remarked with some pride, the Society and its sections held 171 meetings and discussions attended by 6800 members, while the library was visited by more than 20,000 readers, and 3054 parcels of books were sent carriage free to members in the provinces and abroad. Not that he was content with the present position, for he spoke enviously of the recent endowment of the New York Academy of Medicine with half a million pounds jointly by the Carnegie Corporation and the Rockefeller Foundation. This gift was enabling the Academy to maintain a bureau of clinical information and a committee for post-graduate medical education, enterprises both of which the Royal Society of Medicine would gladly undertake, should the means be forthcoming. Mr. Neville Chamberlain, the chief guest at the banquet, in proposing "The Royal Society of Medicine," spoke of the immediate need for the establishment of a post-graduate school in London, and bespoke the good will of the Society for this project. With the help of the committee over which he was to preside as Minister of Health, he thought that the difficulties which had so far baffled endeavours might be surmounted. At the conclusion of the banquet a portrait of Sir John MacAlister, by Mr. Eric Kennington, was unveiled by Miss Williamson, his assistant secretary, and the Jenner medal of the Society was presented to Dr. S. Monckton Copeman.

BERNHARD NAUNY

Bernhard Naunyn was for more than a generation one of the foremost leaders of medical research in Germany, but when he died in July last, at the age of 86 years, he had so long survived his co-workers, and, indeed, many of his pupils, that his death passed almost unnoticed. Naunyn qualified from the School of Medicine in Berlin, he began his long clinical career with Frerichs, one of the founders of the Clinic of Internal Medicine, and succeeded him as the leading exponent of this branch of investigation. In 1871 he founded with Schmiedeberg, at Berne, the *Archives of Experimental Pathology and Pharmacology*, in which his aim was to further the principle of making the clinic itself the arena where pathological questions were solved and applied. He held most emphatically that the problems of illness belonged to the clinician alone, and that although the clinician was indebted for help and method to the physiologists, pharmacologists, pathologists, and bacteriologists, he must be "master in his own house." He was only in Berne for a year, but during that short time he made many close friends, and remained a lover of Switzerland for the rest of his life. His next chair was in Königsberg, and in the year after he occupied it he contracted an ideally happy marriage with his cousin Anna, who survives him after inspiring his best work for 52 years. His time in Königsberg was the happiest and most fruitful of his life. Here he published works, that are now standard text-books, on the echinococcus, toxæmia, fever, and the effect of high altitudes on the hæmoglobin, and laid the foundations of all later work on diabetes and diseases of the liver. He worked from 1888 to 1904 in Strasbourg, and then spent the last 20 years of his life, a period when most men of his age are past work, in research on the colloid chemistry of the gall-stone. The reaction and diffusion of crystalloids and colloids in a colloid medium is at once one of the most interesting and one of the most difficult aspects of colloidal chemistry, and it was Naunyn who first showed that the "facetting" of a gall-stone was due not to pressure from outside, but to a chemical process. His mental acumen remained unimpaired to the last, and he was still equal to the most abstruse chemical problems when he died. He has been described as "a clinician body and soul." He knew that the ultimate application of medical science must be practical, at the bedside, and that science which could not be thus applied was not worthy of the name. As far as speculation solved problems or set them he was not averse from it, but had no use for it in itself. He was one of the most severely practical research workers that there has ever been. He disliked the whole field of modern psychotherapy, holding that to treat it as a separate study was misleading and dangerous, for it was an inseparable part of medical practice. His last published work, entitled "Thanks, Memories and Opinions," is ample proof that he was as good a critic as he was a clinician or an investigator.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CXLIX.—CHRONIC NASAL DISCHARGE AND SINUSITIS IN CHILDREN.[1]

Foreign Bodies in the Nose.

OCCASIONALLY a child pushes a foreign body into his nose without the parents' knowledge. If the object is hard or metallic—e.g., a bead or button—no trouble may arise until years later when a calculus has formed around it which causes obstruction, ulceration, and sanious discharge. On the other hand, when the object is soft or absorbent—e.g., sponge, paper, or wool—it soon becomes a foul purulent focus. The pus trickles from the affected nasal passage, excoriating the nostril, and the breath is fœtid. Headache, aural and other symptoms may also be present. Inspection generally reveals the foreign body, but if it is covered with pus, concealed by the swollen mucous membrane, or offers no resistance to the probe its detection may prove difficult. Under such circumstances, or if the child is young or intractable, a few whiffs of adrenalin solution (1 in 10,000) should be sprayed into the affected nasal passage and a general anæsthetic given. If chloroform is chosen no adrenalin should be applied after narcosis is commenced. A thorough rhinoscopic examination is thus possible, and with a probe search can be made beneath the inferior turbinate and in the upper parts of the nose. The body having been located should be extracted by means of nasal forceps, a hook, or suitably bent probe. All manipulations should be carried out as gently as possible in order to keep the field free of blood.

Chronic Rhinitis.

This term comprises: (1) Affections of the nose, in which the lining membrane has undergone chronic inflammatory changes. These are commonly caused by colds, influenza, the exanthemata, &c., irregularities of the nasal chambers, sinusitis, and adenoids. (2) The groups of nasal signs—the chief of which is hypersecretion—manifested by certain general diseases—e.g., early tuberculosis, intestinal toxæmia, nephritis, &c.

As a rule, when the intranasal changes are slight or absent the discharge is serous or mucous, and when pronounced, muco-purulent. A serous or seromucous discharge is an early sign of simple chronic rhinitis. At this stage of the disease the inferior turbinates swell unduly, causing partial nasal obstruction and secrete excessively, thus giving rise to snuffling and running nose. Colds are readily contracted and the discharge temporarily becomes muco-purulent. In the course of time the congested inferior turbinates undergo hypertrophy. Obstruction and muco-purulent discharge are then constant and the inferior turbinates, even after the application of cocaine, are flabby, especially along their lower edges and at both ends.

Chronic rhinitis is often associated with adenoids and tonsils. When these are removed before the stage of turbinal hypertrophy is reached, cure of the nasal catarrh generally follows. On the other hand, if permanent enlargement of the inferior turbinates has taken place, and is left untreated, the removal of the tonsils and adenoids will not free the child of its nasal symptoms. The frequency of these enlargements has so impressed some rhinologists that the recommendation has been made to reduce the inferior turbinates in every patient operated on for tonsils and adenoids. This is an over-estimate; nevertheless, inquiry should be made in all cases of adenoids as to symptoms of excessive swelling of the inferior turbinates—e.g., pronounced variations at short intervals in the patency of the nose, stuffing in the morning or in a warm room, which passes off on going out of doors, and blocking of one or other side of the nose from time to time. If nasal obstruction and hypersecretion occur independently of adenoids, the parents should be cautioned as to the harmful effects of overheated and close rooms, too little exercise, and too much food. The sending of a city-bred child to the country or of a boy to a preparatory school often dispels all nasal symptoms.

Intermittent obstruction due to turbinal congestion may be benefited, at least temporarily, by a camphor-menthol spray or ointment. A chronic discharge of mucus or muco-pus may be diminished or checked by a nasal wash. For this purpose a warm solution of bicarbonate of soda or common salt (1 drachm of either to one pint of tepid water) is effective. Elaborate formulas made up as powders, tablets, or solutions for the preparation of nasal washes may be found in the lists of manufacturing chemists, but it is doubtful whether these possess specific virtues. Their beneficial action probably is chiefly mechanical. The main requisite in a wash is that it does not irritate the nasal mucous membrane, particularly the olfactory epithelium, and so lead to blunting or loss of the sense of smell. Astringents such as alum and zinc salts are banned on this account.

When the discharge persists or recurs on contracting a slight cold, operative measures may be necessary. The shrivelling of the swollen inferior turbinates by the application of fused chromic acid or the galvano-cautery may suffice. If hypertrophy is established it may be reduced by scissors and snare. This should be done sparingly so that the turbinates may not be undersized when the nose is fully developed. The resection of a deviated septum should be postponed until the patient is at least 17 years of age.

One of the most intractable nasal discharges is that following scarlet fever; it is largely purulent. The inferior turbinates are not enlarged and their lining membrane is not thickened. Nasal washes are only of temporary assistance; mild cauterisation with solutions of chromic acid (10–50 per cent.) afford most benefit. Frequently the antra and several of the other accessory sinuses contribute to the discharge and demand treatment both on this account and because of the recurrent infections—e.g., pneumonia—to which they give rise. When a vasomotor disturbance exists in addition to the turbinal congestion, sneezing may be a pronounced symptom. The obstruction, rhinorrhœa, and sneezing are then usually paroxysmal in character—they set in suddenly, are severe while they last, and cease abruptly. In such cases protein sensitisation and nervous exhaustion must be investigated. When the former can be excluded benefit is most likely obtainable from a course of arsenic.

Some children suffer from a watery nasal discharge which may excoriate the nostrils and upper lip. No turbinal swelling or other intranasal abnormal condition is found. The patients are usually of poor physique and backward; they feel the cold readily, suffer from chilblains, and sometimes from enuresis. Thyroid extract and calcium preparations are indicated in such cases. A unilateral watery discharge is usually due to unequal patency of the nasal passages, especially from deviation of the septum. The discharge comes from the wider fossa when out of doors on a cold day. The application of the cautery or escharotics to the inferior turbinate on this side, unless it is much hypertrophied, is useless or even harmful, because a considerable amount of the discharge is not secreted by the turbinate, but is due to condensation of the moisture in the expired air. The proper treatment is to equalise the patency of the two sides, but when this involves the correction of the deviated septum operation must be postponed, unless the circumstances are exceptional, until the patient is fully grown.

---

[1] An article by Dr. Brown Kelly on Chronic Nasal Discharge in Infants appeared in THE LANCET last week.

Sinusitis.

Anatomical investigations, post-mortem examinations, and clinical experience all go to prove that the accessory sinuses of the nose, even in early infancy, may be the seat of inflammatory and suppurative processes. The infection causing these comes oftenest from tonsils and adenoids, acute colds, measles, scarlet fever, diphtheria, and pneumonia. The commonest symptoms are nasal discharge, obstruction, and cough. Occasionally a severe local disturbance with orbital, intracranial, or other complications arises. In some cases the sinusitis is unaccompanied by local symptoms, but acting as a septic focus causes frequently recurring colds in the head, arthritis, nephritis, laryngitis, pulmonary affections, &c. Dean recommends that if after the removal of tonsils and adenoids, the usual improvement is not obtained, the child continuing listless, pale, with poor appetite, &c., and if, apart from the respiratory tract, the systemic condition is satisfactory, toxæmia should be suspected and search made for a septic focus in the nose or its accessory sinuses.

When the accessory cavities in infants and young children are under suspicion, radiographs should be taken in order to determine which sinuses are present, and their size. Unfortunately, this method in the young is not helpful in diagnosing disease, owing to the pictures of the cavities being ill-defined. The source of a purulent discharge may be discovered by inspection of the nasal fossæ, but oftener no pus can be seen. The pharyngoscope sometimes proves a useful aid. Exploratory sounding, aspirating, and washing may be employed when the sinuses are sufficiently developed. The ethmoidal cells and antrum are of chief clinical importance in the young, the frontal sinus of least. Usually several sinuses on the same side are involved.

The first step in treatment is the removal of the tonsils and adenoids. The improved ventilation which results is followed by the cessation of the sinus discharge in the majority of young patients. Nasal washes and instillations—e.g., argyrol 10 per cent.—should be used to reduce the swelling of the nasal lining membrane and so facilitate drainage of the sinuses. Outdoor life in a warm climate has a beneficial effect. Skillern has found vaccines of greater service in this class of sinus disease than in any other. The ethmoidal cells, frontal sinus, and antrum have been opened and drained in patients even under 3 years of age, but excepting in the case of the antrum such operations are rarely called for. When the patient is over 8 years the antrum can be reached from the inferior meatus and intranasal treatment carried out as in adults. Reference to a radiograph will usually show that this method is not applicable in younger children owing to the floor of the antrum being still too high in relation to the attachment of the inferior turbinate and that attempts to enter the cavity will endanger the rudimentary teeth. For the latter reason the canine fossa route also is not available.

A. BROWN KELLY, M.D., D.Sc. Glasg.,
Consulting Surgeon for Diseases of Throat and Nose, Victoria Infirmary, Glasgow.

Special Articles.

GENERAL MEDICAL COUNCIL.

PRESIDENT'S ADDRESS.

THE winter session of the General Medical Council was opened on Nov. 24th, Sir DONALD MACALISTER presiding.

The PRESIDENT began by paying a tribute to the late Queen Alexandra, and expressed the wish of the Council that on a suitable occasion an assurance of the Council's respectful sympathy and deep regret should be conveyed to Their Majesties. Referring to the retirement, after 15 years' service, of Sir Isambard Owen, the President said that few men in the medical profession in this generation had done so much constructive work of an abiding kind in settling the framework and directing the policy of modern universities. His successor was Prof. Edward Fawcett, Dean of the Bristol Faculty of Medicine, whose distinction and experience made him a welcome member of the Council. The session would mainly be devoted to the hearing of charges against registered practitioners, which were brought before the Council as, in the words of Chief Justice Cockburn, "the tribunal to whom the legislature has left the decision, as being the best judges in the matter."

The Functions of the Council.

"Apart from cases of conviction in the criminal courts," continued the President, "the charges to be investigated allege conduct, which in the words of the Act constituting the Council is 'infamous conduct in a professional respect.' These words are sometimes misinterpreted and misapplied by persons ignorant of their history, sometimes even by advocates practising before this tribunal. It is therefore desirable in the common interest that, from time to time, their legal definition should be recalled. The legal definition was not framed by the Council, it was laid down for the direction of the Council by the Supreme Court, and it was prepared by Lord Justice Lopes, Lord Justice Davey, and Lord Esher, Master of the Rolls, in consultation. It is this :—

> If a medical man in the pursuit of his profession has done something with regard to it which will be reasonably regarded as disgraceful or dishonourable by his professional brethren of good repute and competency, then it is open to the General Medical Council, if that is shown, to say that he has been guilty of infamous conduct in a professional respect.

The Master of the Rolls added further :—

> The question is not merely whether what the medical man has done would be an infamous thing for any one else but a medical man to do. He might do an infamous thing which would be infamous in any one else, but if it is not done in a professional respect, it does not come within Section 29 [of the Act]. Yet, if in relation to his profession—that is, either with regard to his patients or to his brethren—he does that which may fairly be considered 'infamous conduct in a professional respect,' then I think it is within the Section.

"Within the jurisdiction defined by the Statute, according to the procedure laid down by the Lords Justices when giving judgment in certain leading cases, and in accordance with the definition of the technical term 'infamous conduct' furnished by the same authority, the Council performs its statutory duty as a 'domestic forum.' If swayed by fear, favour, or clamour the Council fails to perform any duty vested in it by law for the protection of the public, the Medical Acts themselves provide that the public shall not go unprotected. The Privy Council may issue its directions to the General Council to make good the default, and failing compliance, 'may exercise any power or do any act or thing vested in or authorised to be done by the General Council.' In other words, the Medical Council is a public department, with judicial functions defined by Statute and by the Courts, working under the supervision of the Privy Council, and subject to supersession by the Privy Council if it defaults. It is not vested with any powers or duties for the 'protection' of the medical profession, other than those implied in the preamble to the Medical Act, 1858—namely, 'That persons requiring medical aid should be enabled to distinguish qualified from unqualified practitioners.' For that purpose, which is obviously a purpose of public utility, the Register was set up. The Council's duty to the public is simply to ensure that no one who is not legally qualified by adequate professional training and testing shall get on to the Register, and that no one, who by his conduct has forfeited his claim to be entrusted with the status of a legally qualified practitioner, shall remain on it.

Privileges of Qualified Practitioners.

"The legal privileges of the qualified practitioner of medicine and surgery, as compared with the unqualified, are few. He has no monopoly of practice in either branch, such as the law confers on dentists and midwives in their specialties. The 'privileges' are rather trusts than advantages. Thus only the qualified can legally grant a valid medical certificate of illness or injury, or of death, or legally prescribe a dangerous drug for a patient. In many cases the attestation of a qualified practitioner is legally equivalent to that of a magistrate or a clergyman. These 'privileges' are clearly based on the assumption that members of a learned and honourable profession may be trusted to deal honourably. Whoever, therefore, abuses that trust by misusing the privileges his status confers, or by covertly enabling others for private gain to evade their legal disabilities, is chargeable with misconduct 'in a professional respect,' and makes himself liable to the penalty of removal from the Register. As the law stands, he is then as free to practise as if he had not been registered, and the public is as free to employ him, if they think fit. But the Council, as the guardians of the Register, have neither the power nor the responsibility of controlling his conduct thereafter. His status is that of an unqualified practitioner, and he is outside the Council's jurisdiction. . . .

"There are indications that, both within and without the profession, misunderstandings and confusions exist regarding the Council's functions and limitations. We are, for example, frequently confounded with voluntary organisations and societies of medical men, constituted for scientific and professional purposes, and subserving these purposes with eminent efficiency. These bodies are not, however, charged by statute with our duties and powers, nor we with theirs. We have no professional interest to serve other than the efficient performance of the specific duties laid upon us by the law in furtherance of the public welfare. . . .

Reciprocity.

"As regards Ireland, I have only to say that the Act of the Free State passed in February, 1925, which made the Medical Acts operative in Southern Ireland for one year, has been working smoothly so far as this office is concerned. We have had no official intimation from the Free State Government or from the Privy Council that the Act will be renewed next February. Unofficial communications from members of the Irish Branch Council, and others, indicate that indefinite renewal is improbable, and that conferences on the question are in progress between the Government of the Free State and a Committee representative of the Irish medical profession. Until the legislative proposals of the Government in Dublin for the future regulation of medical practice in Southern Ireland are known, it would be inexpedient for this Council to discuss the potential reactions of such legislation on medical education and registration in Great Britain and Northern Ireland. The Free State is autonomous within its own territory, and we must await the decision of its own Government and Parliament.

"The agreement for medical reciprocity with Italy," continued the President, "had been signed by Signor Mussolini and the British Ambassador, as plenipotentiaries, on May 21st, 1925. Certain difficulties of an administrative kind, which related chiefly to the documents to be furnished by British practitioners desirous of practising in Italy, had been satisfactorily overcome, and the cordial understanding regarding medical reciprocity, which subsisted between Italy and this country from 1910 until the promulgation of the recent Italian law on the subject, had been completely restored.

"The position taken up by the Province of Saskatchewan, by which it, in effect, denied to British practitioners registered here the privileges granted in this country to provincial licentiates, had been the subject of negotiation, and action by the Privy Council in regard to the discontinuance of the unreciprocated privilege of Saskatchewan at present remained in abeyance, in order that every opportunity should be afforded for reconsideration of the anomalous position created by Saskatchewan legislation."

[After referring to the appointment of Col. R. A. Needham as a visitor to Calcutta University and to the fact that the recognition accorded to the degrees of the University of the Punjab were to be continued for another year under the same conditions as before, the President continued as follows] :—

Revision of the British Pharmacopœia.

"The Pharmacopœia Committee is now in a position to proceed with its preparations for the revision of the British Pharmacopœia, 1914, which it has for some time been contemplating. Two recent events have cleared the way. The first is the passing of the Therapeutic Substances Act, 1925, by which Government machinery is provided, in association with the International Commission of the League of Nations, for fixing standards, &c., in relation to preparations requiring biological methods of testing. The second is the issue of the report of the International Conference on Potent Drugs, held at Brussels in September. At this Conference the Council was represented by Sir Nestor Tirard, who will report to the Pharmacopœia Committee its proceedings and conclusions. If the latter are accepted, with or without reservations, by the British Government, this acceptance will necessarily involve modifications, some of them important and far-reaching, in the text of the Pharmacopœia. . . . As the Pharmacopœia has by the nature of the case to serve the purposes of all the parts of the Empire in which it is current, it has to include within its scope a much larger number of drugs and preparations than would be deemed necessary for any one part. A given preparation may be thought obsolete or useless here, and yet be much in demand elsewhere. Any drug, in fact, which is (1) in current use over any considerable area, and (2) requires for the safety of the public that it should be exactly defined, in respect of source, preparation, standard of purity, &c., has a claim to admission. The modern freedom of international communication further makes it expedient that, in different countries, the same or equivalent names, especially in the case of potent drugs, shall mean preparations of equivalent strength and composition. In so far as this end can be attained by international agreement, the assimilation makes for public health and safety. All these considerations have to be kept in mind by the Pharmacopœia Committee; and it hopes, with the assistance which it has invited from authorities at home and overseas, and with the coöperation of its expert Committees of Reference, in the next issue to 'afford to the members of the medical profession and to those engaged in the preparation of medicines throughout the British Empire one uniform standard and guide, whereby the nature and composition of substances to be used in medicine may be ascertained and determined.'"

At the conclusion of the presidential address a vote of thanks to Sir Donald MacAlister, proposed by Dr. J. A. MACDONALD and seconded by Sir NORMAN WALKER, was passed by the Council, which then proceeded to the discussion of reports by the Dental Board and the Dental Education Committee and to the consideration of penal cases.

IMPERIAL CANCER RESEARCH FUND.

THE annual report of this Fund was adopted at a meeting of the General Committee held at 8, Queen-square on Nov. 19th, the Duke of Bedford presiding. In introducing the report, Sir Humphry Rolleston, Chairman of the Executive Committee, summarised the account given by the Director, Dr. J. A. Murray, F.R.S., of the work published from the laboratory during the period under review; this extends to 16 months since it has been decided in future to hold the annual meeting in November rather than in July. Among the 11 papers communicated to general and special journals attention was drawn to one by Dr. W. Cramer on the influence of innervation on the experimental production of skin cancer by tar,[1] and one by Dr. G. M. Findlay on the production of cancer by a single application of tar.[2] Dr. Cramer deprived a skin area in a number of mice of the nerve-supply and then painted it twice weekly until cancer supervened. This only occurred after a longer course of tarring than was necessary in normal animals, and, therefore, absence of nerve-supply certainly does not predispose to the genesis of cancer as has been suggested. The nerves grow again into the denervated area, so that the experiment does not give an absolute answer to the question, whether, if renewal of the nerve-supply could be prevented, cancer would not be produced at all.

Dr. Findlay's experiments were devised to determine if it is possible to reproduce in animals the remarkable sequence reported in the human subject from time to time, in which an accidental tar burn has been followed after a short interval by the appearance of typical progressive carcinoma at the point of injury. For this purpose a large number of mice received a single application of hot tar on a small area of the back. A slight swelling and reddening of the skin followed but soon subsided. It was not till the lapse of a year that any further change was observed, and then three mice showed typical cancer of the skin in the site of the application. This experimental result is important in that it shows that general intoxication with tar, which has been invoked by many workers as an important factor in the causation of tar cancer is, to say the least, not essential. Dr. Findlay is also continuing his research into the action of manganese salts, especially as regards the more delayed effects, but has not published any further report in the year under review.

The work under the Atholstan Grant for research is being carried on with great diligence by Dr. A. M. Begg. His investigations on the Rous fowl sarcoma and the infective lymphosarcoma of the dog have inevitably taken on a new orientation since the publication of the work of Dr. W. E. Gye, of the Medical Research Council. Dr. B. R. G. Russell took a keen interest in this work, and since his lamented death Dr. Begg has had the advantage of close association with Dr. Gye. This informal collaboration has been a source of great satisfaction to the Executive Committee. Dr. Begg's investigations are progressing satisfactorily and it is hoped will soon be ready for publication. The important work of Dr. Gye and Mr. Barnard, in addition to the many new lines of inquiry it opens up, calls for the most careful repetition with as many different kinds of tumours as possible. This is now occupying much of the time and energy of the scientific staff.

The Duke of Bedford made sympathetic reference to the loss entailed by the deaths of Dr. Sidney Martin, F.R.S., and of Dr. B. R. G. Russell, for 17 years a member of the scientific staff. As to the report of the hon. treasurer, Sir George Makins, he pointed out that the expenditure had exceeded the fixed income of the Fund—that is, the income derived from investments—by £1765. Subscriptions and legacies had made good that adverse balance, but to be compelled to rely on subscriptions and legacies for carrying on the work of the Fund was always unsatisfactory. He called attention to the list in the Director's report of workers in different parts of the world to whom material has been supplied from the laboratories of the Fund. The ability of the Fund to assist in the investigation of cancer in other laboratories, and the willingness of the staff to do so seemed a most practical way of making collaboration in research really effective, especially as it did not encroach in any way on the freedom of the workers. But this service was often a very laborious one, took up a great deal of the time of the workers, and consequently entailed a considerable addition in working expenses. But it was an increase in expenditure which was a legitimate source of satisfaction inasmuch as it means furthering research throughout the Empire. It was satisfactory to learn that the Stroud Laboratory (at Mill Hill) had been completed, that full opportunity could now be given to carrying out research under Lord Atholstan's gift, and that papers relating to the subject of this research might shortly be expected.

Sir Thomas Barlow, Bart., was nominated for re-election by the Royal Colleges of Physicians and Surgeons as a member of the Executive Committee, and Prof. William Bulloch, F.R.S., and Prof. A. E. Boycott, F.R.S., were re-elected members of the same Committee.

THE GENEVA OPIUM CONFERENCES AND THE HAGUE CONVENTION.

AN epitome of the work accomplished at the two prolonged Opium Conferences at Geneva has already appeared in THE LANCET,[1] and full official records [2] of the proceedings and a special Foreign Office report [3] have now been issued. It will be remembered that the first of the two conferences purported to deal only with the suppression of opium-smoking (Chapter II. of The Hague Convention), while the second conference was concerned with the abuse of morphia, cocaine, and other drugs of addiction (Chapter III. of The Hague Convention). Again and again in the course of the debates it was manifest that this artificial dissection of The Hague Convention and the reference of its chapters to two different conferences had no logical justification, and indeed caused considerable confusion leading to the regrettable withdrawal of the United States delegation, followed by that of China. This unfortunate dichotomy occasioned lengthy and somewhat pedantic discussions as to the competence of one conference to encroach on the reference to the other, and to the unpleasant suggestion that the first conference (which included only representatives of countries concerned with "prepared" or smoking opium) was in fact "a prepared opium bloc" whose members were seeking to release themselves from their obligation under The Hague Convention (Article 6) to bring about the effective suppression of "prepared opium." The American delegation contended for the limitation of the production of opium so as to preclude the use of it or its products for other than medical and scientific purposes. This general principle had been endorsed by the Advisory Committee of the League of Nations on the traffic in opium as being the basis of The Hague Convention of 1912, and the Fourth Assembly of the League had requested the Council of the League to give effect to this principle and to summon a conference for that purpose. It is true that the delegate for India made reservation as to opium-eating as practised in that Dependency not being regarded as illegitimate, and this reservation occasioned considerable difficulty in relation not only to production of opium in India but also to the invasion of sovereign rights by international engagements.

The attempt to discriminate between opium-eating as harmless or even beneficent, opium-smoking as a "social vice," and addiction to morphia or its derivatives, has not received scientific or pharmacological justification; while the finding of the Joint Health and Opium Subcommittee of the League of Nations, "that the medical use should be considered the only legitimate use," probably represents the best and informed opinion. When Lord Cecil appeared on the scene as first British delegate on Jan. 19th, 1925, he used all his forensic efforts to separate the work of the two conferences, urging that "opium-smoking had nothing whatever to do with the question of drug addiction." Yet he admitted that "unless growth and production are controlled it will be very difficult to control the use of drugs," and again he said, "it is quite true that a good deal of Indian opium is exported for the purpose of smoking." Much of this Indian-grown opium goes to Crown colonies for smoking purposes, and Sir Malcolm Delevingne in his report to the Foreign Office, says:—

> "The fact that a very considerable proportion of the revenues of certain of the Crown colonies is drawn from the traffic in opium-smoking, which is a criminal offence in the self-governing parts of the British Empire and which His Majesty's Government is internationally bound to suppress, lends colour to this allegation. . . . It is doubtful whether, even among the neutral delegations who were not prepared to support the United States proposal, that feeling has been dissipated. It is certain that the United States held it strongly. It is a point of which more will undoubtedly be heard."

At times the fate of the two Geneva conferences was pronounced to be "critical." An attempt to remove the "deadlock" by reference to a joint delegation or commission of the two bodies led to an inconclusive result, and Lord Cecil was constrained to admit that it would very likely have been better not to have had two conferences but one. The final protocols and convention elaborated by the two conferences have already been published and criticised. The suppression of opium-smoking, envisaged by Chapter II. of The Hague Convention, is to take place within 15 years from a date, to be determined by a League of Nations' Commission, when smuggling of opium from producing countries shall have ceased to be a serious obstacle to the enforcement of restrictive measures. A group of opium-producing countries, of which China was not one, agreed to take such measures within five years. A new convention made some additions to The Hague Convention, e.g., the inclusion of coca leaves and Indian hemp, empowered the exclusion of certain preparations, and established a Permanent Central Board to receive information, to compile statistics, to watch international trade, to ask for explanations to publish reports thereon, and communicate them to the Council. All these provisions are dependent on the ratification of the convention (the period for signature closed on Sept. 30th) by ten Powers, including seven who are accorded representation on the Central Board, of which two must be members of the Council of the League.

Some who have reviewed the work of the Geneva conferences find consolation in thinking that an advance has been made even though, as Mr. Zahle, the able President of the second conference, admitted, the attempt to limit production to medical purposes was not successful, and on the definite suppression of opium-smoking no agreement was reached. Mr. J. P. Gavit, who attended every session of the conferences, concludes [4] that "the agreement of the first conference represents no progress worth discussing, and the new drug convention adopted by the second is a thing of printed paper with the odds heavily against its ever being anything else." Prof. W. W. Willoughby, who acted as technical expert to the Chinese delegation, considers [5] that "the initial mistake" was providing for two conferences instead of one, and he holds that "little substantial result is to be expected" from the protocols arrived at. Other writers, including Sir William Collins,[6] and Prof. Perrot,[7] from the French point of view, have also commented on the results. In a pamphlet entitled "Public Health Aspects of the Narcotic Problem," which has reached us from China, Dr. Wu Lien Teh, who speaks with first-hand knowledge of the Far East and was one of the delegates of China to the first Hague Conference, laments the conclusion of the Geneva Conference which made suppression of opium-smoking contingent upon the success of efforts against smuggling. He disputes the alleged virtue of opium against plague, malaria, and tuberculosis, or the necessity of opium-smoking for the Chinese or opium-eating for the natives of India. He alleges that morphia has been and is smuggled into China by the ton, much of which is derived from European countries. It is to be regretted that the legislative results of The Hague Convention in Great Britain in the shape of the Dangerous Drugs Acts, and in the United States in the shape of similar statutes, cannot be given wider and international application, for no one disputes that the production of opium, morphia, cocaine, and other "habit-forming" drugs is grotesquely in excess of any conceivable medical or scientific requirement, and that the surplus output is prostituted to purposes of vice and crime, and to the degradation and demoralisation of the pliant victims of addiction to these dangerous drugs.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Sanitary Condition of School Buildings in the Irish Free State.

Mr. T. Johnson, leader of the Labour Party in the Dail, recently asked the Minister of Local Government to give some definite statement of his intention with regard to putting the school buildings into habitable condition. The Minister, in reply, said that the management of the school was responsible for upkeep; the schools were not State schools, but State-aided schools. It was evidently not possible, without changing that system, to impose by the authority of the State a system of local maintenance, whatever might be done to encourage it.

The Minister's answer shows for the first time in history any official appreciation of the responsibility of the State for the sanitary condition of the schools. It has long been recognised that many of the school buildings in all parts of Ireland were unsuitable and insanitary and likely to cause disease among the children crowded into them. The fact that the local manager was legally responsible for the condition of the school premises rendered the central education authority slow to interfere. Indeed, a former chief official of primary education in Ireland, when a demand was made on him by a committee of persons interested in the public health that his department should exercise some control over the sanitary condition of the schools, ridiculed the suggestion, and declared that he and his department were concerned only with the minds of the children and not at all with their bodies.

Enforcement of Vaccination.

For some months past the Department of Local Government and Public Health of the Irish Free State has been endeavouring by means of persuasion to induce the Health Board of Co. Wexford to enforce the laws concerning vaccination. These exertions seem to have been useless, and the Department has at length been compelled to adopt stronger measures. The Health Board was notified last week that the Minister had issued instructions to the Chief State Solicitor to take proceedings by way of mandamus to compel the Board to carry out its legal obligations. The Minister adds that the names of the members who had voted against the enforcing of the law had been furnished to the State Solicitor in order that they might be named as special defendants and that costs might be recovered from them personally. The letter of the Department was marked "Read." The question of compulsory vaccination was also raised in the Dail last week, when, in reply to a question, the Minister said that he did not intend to introduce legislation to abolish compulsory vaccination, but that he proposed to enforce the existing law.

False Economy.

The authorities of two asylums in the Free State propose to save money by measures which are likely to interfere seriously with efficiency. At the Grangegorman Mental Hospital proposals of economy put forward by a subcommittee were adopted. Among these proposals were a 10 per cent. reduction of the salaries of all employees, and reductions in the yearly increments and long service pay. It seems that a proposal was also made to lengthen the hours of duty of attendants and nurses, but the subcommittee did not accept this. The present working week consists of 56 hours. It is, of course, doubtful how far the Committee of Management has power to alter existing rates of pay, which must, in some cases at least, be matters of contract. The mere proposal, however, is bound to give rise to discontent. In Mullingar Mental Hospital an even more dangerous experiment is to be tried whereby not only the salaries of employees but the dietary of the patients would be curtailed. It is to be hoped that the Department of Local Government will refuse to sanction a dietary strongly condemned by the medical officer, who is primarily responsible for the health of the patients.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Foreign Patients in the Hospitals.

THE chiefs of the Paris hospitals have been struck by the increasing number of aliens whom they attend as patients in the wards. In this connexion Dr. P. E. Weil quotes statistics from the Hôpital Tenon to show that in a period of six months (the last quarter of 1924 and the first quarter of 1925) there received treatment, in medical and surgical wards together, 8321 French people, as compared with 537 aliens, respectively 93·6 and 6·4 per cent. The points of inquiry were the length of time these foreign patients had been in France, their state of health previous to their arrival in the country, the work they had done since their arrival, whether they were suffering from temporary or chronic illnesses, their family responsibilities, and finally their social status. 33 per cent. suffered from curable complaints, 66 per cent. were affected with conditions which more or less seriously diminished their earning powers, and many became a charge on the Assistance Publique. Almost all the foreign patients had been in France for several months, some for several years. There were many cases of old-standing tuberculosis, and many patients had been infected long before their arrival in France. Tuberculosis and chronic bronchitis are of frequent occurrence among natives of Tunis and Morocco, who do not readily become acclimatised in France. In three cases syphilis was found to be of very old standing, but its visceral manifestations were so extensive as to render the patients useless for work. Of the total of foreigners, two-thirds were single, but one-third were married with families. Thus the number of aliens under treatment in the Paris hospitals is considerable, and as many have chronic diseases which render them non-productive to the State they become a burden on the community. Further, a certain proportion of these patients are carriers of infection, particularly of pulmonary tuberculosis. There is, therefore, some need of measures to control immigration and ensure the possession of a certain "fund of health" by those who enter France. To this end the Academy of Medicine has nominated a commission which will give full consideration to the question and outline suitable measures for reform.

Serum Therapy for Poisoning by Mushrooms.

Dr. Dujarric de la Rivière has been for several years conducting researches on animals experimentally poisoned with non-edible mushrooms of the genus Amanita (*A. phalloides, verna, virosa, citrina*) to test the efficacy of the serum of horses immunised by progressively increased doses of the extracts of such fungi. This serum, which he has named "sérum antiphallinique," and which has given encouraging results on the experimental animals, has recently been tried out in man. The effects of the serum were sufficiently satisfactory to justify further trials being made, first because at present there is no adequate therapeusis of fungal poisoning, and secondly because it appears that the use of the serum is not attended with any risk. Treatment should be begun as early as possible after ingestion of the poisonous mushroom and should be administered by the intramuscular route. The exhibition of the "serum antiphallinique" does not interfere in any way with the employment of the usual therapeutic measures, such as cardiac tonics. It would be of advantage if this serum was available at all treatment centres and particularly in the hospitals to enable further tests to be made, where doctors might obtain it when necessary.

Tuberculosis in France.

In France tuberculosis was a grave menace before the war, and the war only increased the dangers of its spread through female labour, insufficient feeding, increased exposure, and abnormal expenditure of bodily energy. The intensive campaign against this disease, initiated by the Rockefeller Foundation, has been continued with excellent results, according to the report of the National Committee against Tuberculosis. In 72 of the French Départements 530 dispensaries are now in active operation. Since the campaign was opened consultations have numbered about 495,000 per annum, the sputum examinations 81,000, and the number of patients placed in conditions favouring good treatment 28,000. The mortality from tuberculosis, which was rising in 1916 and 1917, declined from 1918 to 1920, falling from 278 to 185 per 100,000. Since 1920 no State money has been available for maintaining the statistical records of tuberculosis in France. The *Matin* assigns this unfortunate condition of things chiefly to rivalry between Government bureaus. It appears that the task of keeping the tuberculosis records was transferred from the general statistical bureau to the Ministry of Hygiene, which failed to receive a corresponding budgetary increase.

MEDICINE AND THE LAW.

Workmen's Compensation: Epithelioma of the Scrotum in a Cotton-Spinner.

MEDICINE and the law are probably in agreement over a decision of the county court judge at Oldham in respect of a spinner who had suffered from epithelioma of the scrotum, an occupational disease on which interesting observations have been recorded by Dr. Alexander Scott and Dr. E. L. Kennaway amongst others.[1] From the account published in the *Oldham Evening Chronicle* it appears that the employers did not dispute that the workman acquired the disease through the nature of his work as a cotton mule spinner. He had undergone an operation which the employers contended had been entirely successful. The point at issue between the parties was whether he could be expected to go back to his former employment or not. If not, then he would sink from the wage-level of a skilled workman to that of an unskilled workman and compensation would have to be assessed on the basis of the consequent difference in his earnings. Medical evidence for the applicant expressed the opinion that the fact of his having had the disease indicated that he was predisposed to the action of the mineral oils in that particular kind of employment and that therefore it could not safely be said that cancer would not return. This view was ultimately admitted by the medical witnesses called on behalf of the other side. As soon as this point was conceded, there was an end of the case. For the employers it was stated that other men with a similar history had returned to their old work without recurrence of the disease. A doctor testified that the applicant had been certified last April to have sufficiently recovered to be fit for work, and that on recent re-examination he was found to be a sound and healthy man so far as the operation was concerned. The learned judge pressed this witness to know if any medical expert would stake his professional reputation on the non-recurrence of the disease. Naturally no one was prepared to go so far. The judicial attitude is worth noting as a guide for future cases of this kind.

---

[1] THE LANCET, 1925, i., 932–3.

His Honour: Do you think he is a person predisposed to this disease?

Dr. Carr (called by the respondents): I don't think I quite agree with those words.

His Honour: Then how is it that of all these people who work on these mules he should get it? Why should he be singled out? By providence or what?

Dr. Carr (after consideration): I think you must say he is predisposed to it.

His Honour: Knowing a man is predisposed to a disease, would you recommend him to go back to the place and occupation where he got the disease?

Dr. Carr: No.

This was a fair and candid answer, and it meant that the employers could carry their case no further. The learned judge, who, it must be remembered, does not sit regularly in a town like Oldham without acquiring considerable experience in cases of industrial and occupational disease, assessed the applicant's present earning capacity at 38*s.* per week and awarded 6*s.* 11*d.* per week compensation. The principle of the decision seems to be well established, and it is difficult to see how it could be reviewed upon appeal.

The Services.

ROYAL ARMY MEDICAL CORPS.

Maj. E. M. Pennefather to be Lt.-Col., Capt. W. P. Croker to be Maj. to complete estabt.

Capt. G. O. F. Alley is granted the temp. rank of Maj. whilst empld. as a Dep. Asst. Dir. of Hygiene and Pathology.

SUPPLEMENTARY RESERVE OF OFFICERS.

Maj. H. B. Walker, late temp. Maj., R.A.M.C., to be Capt.

TERRITORIAL ARMY.

Capt. G. W. B. Shaw, R.A.M.C., to be Divl. Adjt., 44th (Home Counties) Divn. T. A., vice Capt. S. D. Reid, R.A.M.C., who vacates the appt.

Capt. H. A. Sandiford, R.A.M.C., to be Divl. Adjt., 49th (West Riding) Divn., T.A., vice Capt. C. Popham, R.A.M.C., who vacates the appt.

General List: Lt. Horace Smith Ward (late M.G. Corps) to be Lt.

Sanitary Companies: Lt. G. W. Wright to be Capt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Capt. J. C. Robb (supernumerary for serv. with the Belfast University Contgt., O.T.C.) from the Active List, to be Capt.

ROYAL AIR FORCE.

The undermentioned are granted short service commissions as Flying Officers, for three years on the active list: G. M. Anderson, B. L. Edwards, and W. D. McKeown.

Flying Officer R. W. White is promoted to the rank of Flight Lt.

INDIA AND THE INDIAN MEDICAL SERVICES.

Lt. C. Hudson to be Col.

Des Raj Nayar to be temp. Lt.

The King has approved the grant of a temporary commission to Harbans Singh.

His Majesty has also approved the relinquishment of their temporary commissions by Capt. Priya Nath Lahiri, who is permitted to retain the rank of Capt.; Capt. Ramesh Chandra Basu, who is permitted to retain the rank of Capt.; Lt. Mir Abdul Basir, who is permitted to retain the rank of Lt.; and Lieut. Fakhar-ud-Din.

Capt. M. Moosa Khan has been appointed Superintendent of the Central Jail, Cannanore, vice Maj. J. C. Bharucha, who reverts to the Madras Civil Medical Department; Lt.-Col. A. W. Overbeck-Wright, on return from leave, has been reposted as Superintendent of the Mental Hospital, Agra. On return from leave, Capt. J. H. Smith has been reposted to charge of the Mandalay Central Jail in relief of Maj. J. Findlay, who has been appointed Superintendent, Insein Central Jail at Mandalay; Capt. A. J. De Souza will act as Civil Surgeon, Cochin.

Revised Rates of Furlough Pay in India for Regular Executive Officers of the Indian Medical Service in Military Employ.

The furlough pay in India of regular executive officers of the I.M.S., while on leave in India, other than privilege leave, will be at the monthly rates given below, to which full overseas pay will be added, when admissible.

Lieutenants	Rs. 375
Captains—	
During first three years' service as captain ..	500
With more than three years' service as captain	600
With more than six years' service as captain	700
Majors—	
During first three years' service as Major. ..	750
With more than three years' service as major ..	900
With more than six years' service as major ..	1050
Lieut.-Colonels—	
Until completion of 23 years' total service ..	1200
During twenty-fourth and twenty-fifth years of service	1300
After completion of 25 years' service	1400
When selected for increased pay..	1550

These revised rates of pay will have effect from Jan. 1st, 1926.

WEST AFRICAN MEDICAL STAFF.

The following appointments are announced: Dr. M. W. Fraser, medical officer, Gold Coast, to be a Senior Medical Officer in Nigeria in succession to the late Dr. J. A. Beamish; Dr. S. Goodbrand, medical officer, Gold Coast, to be a Senior Medical Officer in Nigeria to fill the vacancy caused by promotion of Dr. J. M. Pollard, to be an Assistant Director of the Medical Service in that Colony; and Dr. J. E. Moffatt, medical officer, Gold Coast, to be a Senior Medical Officer in that Colony in succession to Dr. R. O. White who has retired.

Surg. Comdr. H. E. Yeo White, M.V.O., R.N., has been appointed, on the occasion of the visit of H.R.H. the Prince of Wales to Africa and South America, an officer of the Civil Division of the Most Excellent Order of the British Empire.

DEATHS IN THE SERVICES.

Colonel John Lloyd Thomas Jones, I.M.S., retd., brother of Sir Robert Armstrong-Jones, died at his residence in London on Nov. 12th, aged 62. The fourth son of the late Rev. Thomas Jones, of Eisteddfa, Criccieth, he was a student at St. Bartholomew's Hospital and graduated in medicine at the University of Durham in 1885, in which year he also obtained the M.R.C.S. Eng. Two years later he entered the I.M.S., became Captain in 1888, Major in 1899, and Lieut.-Colonel in 1907. In India he first acted in medical charge of the 3rd Beloochistan Regiment at Mhow, later performed similar duties with the 23rd Bombay Light Infantry, and afterwards with the 16th Bombay Infantry; respectively at Karachi, Malegaon, Seetabuldee, and Kamptee. For some time he was in civil charge at Ratragiri and Karwar, when he was again transferred to military duties, serving with the 7th Bombay Lancers in Quetta, and with the 14th Bombay Infantry at Cutch-Bhuj. He afterwards acted as civil surgeon at Kaira, Broach, and Aden. In 1897 he was appointed on famine duty, serving as deputy sanitary commissioner and special plague officer at Poona. By his tact and special knowledge he overcame the native prejudices against segregation, and for these services received the special thanks of the Government of India. In 1899, after leave in England, his services were transferred to the Finance Department of the Government of India and he was appointed Deputy Assay Master to H.M.'s mint in Calcutta, and in 1908 he was transferred to the mint at Bombay as Assay Master. He served at Calcutta and Bombay until his retirement in 1918, when his continuous and devoted services to the British and native officers were recognised by a presentation of gold and silver plate. Colonel Lloyd Jones was a Fellow of the Geological Society, of the Institute of Chemistry, and of the Chemical Society of London, and a member of the Institution of Mining and Metallurgy. He was a member of the Order of St. John of Jerusalem, and during his residence in Bombay served as one of the justices of the peace in that city. A keen horseman and a good judge of horses, he excelled in polo and was well known in Bombay.

Public Health Services.

SCHOOL MEDICAL SERVICE.

THE following are figures for 1924 :—

Name of district.	No. on roll.	Average attendance.	Routine inspections.	No. examined in "code" groups.	Special and re-inspections.	Percentage found on routine examination to require treatment.
Liverpool.	Not stated.	Not stated.	39,098	—	78,986	19·7
Carlisle ..	8,024	7,129	—	2,544	1,516	33·3
Hastings .	6,751*	6,142*	2,163†	—	8,024	18·4
Tunbridge Wells ..	Not stated.	Not stated.	208	701	1,475	20·5

* These are the figures for last quarter.
† In addition 60 other reinspections.

Liverpool.

In his introduction Dr. A. A. Mussen, medical officer of health and school medical officer, mentions four directions in which he looks for further progress —namely : (1) The provision of more open-air education for delicate children, of whom there are a large number in Liverpool. (2) The extension of the scheme for dental treatment, as out of 89 public elementary schools in the city placed on the list for treatment it was only possible to deal with 62. The number of children examined showed, however, considerable increase, being nearly twice as many as in 1921, and the number of parents accepting treatment showed a marked increase. (3) Increased facilities for dealing with the question of uncleanliness. On this subject Dr. Mussen points out that infestation with vermin is in the majority of cases a family condition, and he shows that a satisfactory scheme for dealing with the problem on a large scale involved : improvement in the housing and domestic facilities ; the enlightenment of the public and the setting of a higher standard ; increased public facilities for cleansing—e.g., the use of large spray baths. (4) His fourth desideratum is the reopening of a class for stammering children which was discontinued during the war. In general, the organisation for inspections and treatment seems quite satisfactory ; for example, we note there are six special schools for mentally defective and physically defective children, and there are two classes for children of defective vision. There is an interesting note on 57 children suffering from the after-effects of encephalitis lethargica, and Dr. Mussen shows how these may take the form of paralysis of Parkinsonian type in a few, of mental defect in a few others, but that in others (the great majority) the essential feature is character change. We agree with Dr. Mussen that it would be inadvisable to certify these children either as mentally defective or as lunatics, and that the right method is to certify them as physically defective, but to deal with them apart from the ordinary physically defective child.

Carlisle.

The report of Dr. Joseph Beard is short but full of statistical tables. It may be doubted whether sufficient attention is attracted by these tables ; short comments might make them more interesting to both lay and medical minds. There is a noticeable decrease in the figures for defective vision, and Dr. Beard suggests that this may be a result of changes in the curriculum. There are no schools for the physically or the mentally defective. The report deals with open-air education at some length and is very instructive. The "Newtown delicate class" presents some interesting features. There is a fair sprinkling of tuberculous cases in the class, and 15 children received injections of tuberculin B.E. out of 83 children dealt with in the class. The items o cost for this class are illuminating, the average total per child being only 8*d.* per day.

Hastings.

Dr. G. R. Bruce, medical officer of health and school medical officer, publishes his school and general public health reports together, and it is evident that the coördination now in force is very complete. For example, the borough is divided into four districts, each with a health visitor, the scope of whose activities is very large and who also does the school work, so that, as Dr. Bruce says, "the nurse with continuity of office may follow the children from birth to the end of their school days, while the long-suffering mother has one visitor the less." Each nurse has also an infant welfare centre in her district, while each half of the town is served by an antenatal centre. There is cordial cöoperation with the many activities of the voluntary associations which Hastings is fortunate in possessing. Dr. Bruce is responsible not only to the Education Committee for the mentally defective school-children, but also to the Mental Deficiency Act Committee for other persons. There is a special school for mentally defective children at Hollington doing good work ; it is benefited by the recent establishment of an occupation centre for lower grades. There is at present no school for the physically defective. Crippling of severe degree is uncommon in Hastings, thanks to the comparative absence of acute poliomyelitis, rickets, and surgical tuberculosis. There are, however, several mild cases, and the solution is an orthopædic scheme together with the open-air school, which is now being considered by the Education Committee and should soon materialise.

Tunbridge Wells.

Dr. F. C. Linton, medical officer of health and school medical officer, includes school work in his public health report, and deals with it briefly. Coördination is, he states, complete, since he is responsible for child welfare and the care of debilitated children under school age as well as for school-children. He considers that the increased treatment of tonsils and adenoids may be a factor in the reduction of the incidence of infectious disease ; a similar opinion has been expressed in other areas. We are sorry to see there are no special schools in the area, though Dr. Linton states that, using the term in a very broad sense, there are 113 physically defective children. Sixteen of these are, however, attending a private and voluntary open-air school provided by the kindness of a lady resident.

TUBERCULOSIS SERVICE.

YEAR by year the county councils and the county boroughs find themselves bearing a larger and larger share of the tuberculosis work of the country, and we note the welcome tendency for reports of tuberculosis officers to become more informing and valuable.

The report of the central tuberculosis officer of the *Lancashire County Council* for the year 1924 gives an extensive survey of the conditions of tuberculosis in the county. Details of death-rates, notifications, radiological investigation, research work, propaganda and education of the public, housing conditions, after-care, new hospitals and dispensaries, are all dealt with at considerable length. One of the most interesting sections of the report is devoted to radiological work in which the value of X ray examination in diagnosis and treatment of tuberculosis is emphasised. X ray installations have now been increased so that there is one dispensary in each area equipped for this purpose, and over 4000 radiological examinations have been made during 1924, in comparison with less than 200 in 1920 when the first installation was made. The radiograms given in the report show that the tuberculosis officers of Lancashire possess a wealth of clinical material of which they make good use. A considerable amount of research work is being done and no less than nine special methods of treatment have been investigated. As the central tuberculosis officer points out, the results of these investigations do not show that any drug or preparation can be regarded as definitely beneficial in the treatment of tuberculosis, yet the time spent by the staff has been by no means wasted but rather valuable experience has been gained. The report shows that a further decline in deaths from tuberculosis and new cases notified occurred during the year 1924, the death-rate being the lowest so far recorded.

The report for the *City and County of Newcastle-upon-Tyne* shows a definite decrease of the notifications for the year for the first time since the introduction of compulsory notification. The figure for pulmonary tuberculosis in adult females exceeded that for adult males, and is the highest recorded since 1912. The tuberculosis medical officer considers that the adverse economic condition of recent years has been a contributory factor in this result, but suggests that there may be other explanations still to be found. The report also contains a record of institutional treatment at Barrasford sanatorium, where early or moderately advanced cases of pulmonary tuberculosis are treated; at the sanatorium pavilions of the City Hospital, where more advanced and emergency cases are dealt with; and at Stannington sanatorium, where tuberculous children are cared for. Statistical tables are given showing the previous occupation of patients, the average number of beds occupied, and the number of patient days, results of treatment, and other important details.

In the report on tuberculosis for 1924 from the *Public Health and Housing Department for Birmingham* figures are given showing the mortality from tuberculosis in 1923 of eight other large towns in Great Britain with which to compare the Birmingham figures. The mortality-rate per 1000 of all forms of tuberculosis in these towns shows that Birmingham occupies a very favourable position. The report emphasises the advantage which Birmingham possesses in having sufficient beds for the work. Interesting statistics are given showing the working capacity of patients when first examined, newly notified cases, old cases, "suspects" and "contacts," and a section showing results of dental treatment. The services of a part-time dental surgeon are utilised and the treatment consists mainly of extractions, fillings, and scalings. It is very encouraging to find this important aspect of the tuberculosis problem so carefully dealt with. The report also devotes a section to the new light treatment department which has been installed.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED NOV. 14TH, 1925.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 73; scarlet fever, 2262; diphtheria, 1052; enteric fever, 67; pneumonia, 889; puerperal fever, 37; cerebro-spinal fever, 4; acute poliomyelitis, 6; acute polio-encephalitis, 1; encephalitis lethargica, 43; continued fever, 1; dysentery, 2; ophthalmia neonatorum, 93. There were no cases of cholera, plague, or typhus notified during the week.

Deaths.—In the aggregate of great towns, including London, there were 6 deaths from enteric fever (none in London), 34 from measles, 5 from scarlet fever, 29 from whooping-cough, 28 from diphtheria, and 44 from influenza. In London itself there were 8 deaths from diphtheria and 17 deaths of infants under 2 years of age from diarrhœa and enteritis (a substantial fall from previous weeks).

LACK OF SMALL WARDS.—The Minister of Health has drawn the attention of the guardians to the lack of small wards in Lambeth Poor-law Infirmary and to the consequent difficulties of administration. Stress is laid on the value, for instance, of small wards in the treatment of puerperal fever. At Lambeth such cases have to be treated in large wards, and the Minister points out that the advantages of treatment in small ones apply to other diseases besides that mentioned, and suggests that the guardians should consider the adaptation of an existing block at the institution for such purposes.

INOCULATION AGAINST THE COMMON COLD.

To the Editor of THE LANCET.

SIR,—Dr. A. I. Simey's address on the prophylaxis of the common cold and febrile catarrhs in your last issue will be of great interest to all who are responsible for the care of children at boarding schools. Dr. Simey understates rather than overstates the importance of this matter as, in addition to all those who come under the care of the school medical officer for catarrhal infections, there are always a considerable number who suffer from colds without pyrexia, and who fail to report to the house matron or medical officer lest they be put off games. These minor cases, although less serious to themselves, are fruitful sources for spreading the infection.

Dr. Simey's bold suggestion concerning prophylactic inoculation in boarding schools deserves the consideration and support of school medical officers. The fact that inoculation with certain specific bacteria is advocated does not mean that these bacteria must be accepted as the primary cause of the disease. It is conceivable, and perhaps even probable, that the primary cause, if unattended by secondary infections, would be negligible. With regard to the details of his suggested experiment, I think that it is important that vaccines should be made from recently isolated cultures from acute infections, and that the vaccines should be of recent date—say not more than four months old.

With regard to the organisms which should be included in the vaccine, there will be some difference of opinion, but if several large schools are carrying out such an experiment in conjunction with different laboratories, valuable statistical evidence may be obtained on this point. Dr. Simey's suggestion of inoculating during the summer and Christmas holidays would, I think, be unsatisfactory. In the summer holidays no large numbers of recent cultures would be available, and few parents would be inclined to go to the necessary trouble during the summer months when they and their family are probably away from home and out of reach of any doctor they know. Similarly, it would not be popular to disturb the round of Christmas-time festivities. The whole matter would more simply and efficiently be carried out by the school medical officer.

I would suggest, therefore, that two inoculations should be given during the first half of October, and again two in the second half of January. This would enable the vaccine to be made up from the first batch of catarrhal infections which usually occur towards the end of September, and also allows for the probability that artificial immunity to the bacteria in question is in many cases of comparatively short duration.

I am, Sir, yours faithfully,

London Hospital, E., Nov. 23rd. G. T. WESTERN.

NASAL LAVAGE AND ACUTE MIDDLE-EAR INFLAMMATION.

To the Editor of THE LANCET.

SIR,—Acute middle-ear inflammation and its complications, due to nasal lavage in some form or another in healthy and unhealthy noses, has become so frequent that the subject requires thorough examination and ventilation. The usual reasons given for nasal lavage when there is nothing whatever the matter are that it keeps the nose clean and clear, and prevents infection. The Ministry of Health must accept part of the responsibility, for, in one of the recent influenza epidemics, they advised it as a preventive measure. It does not seem to be realised that the lining membrane of the nose is a very delicate thing and possesses the functions of warming, moistening, and purifying the air passing over it; in these functions the ciliæ, mucous glands, and blood-supply play a large part and the application of any unnatural material must hinder them in their work—at first overstimulating and then temporarily paralysing them. Patients often say, "But you should see what a large amount of stuff comes away after doing it," thinking they are getting rid of a collected nasty discharge, and not realising that the nasal mucous membrane, by pouring out the extra normal mucus, is protesting as vigorously as it can against the outrage inflicted upon it. It is quite common for repeated attacks of acute middle-ear inflammation to result from some of the injected solution passing up the Eustachian tube. It should be generally known that the healthy nose is hindered in its work by the application of anything unnatural and the danger to hearing and life is a very real one.

Nasal lavage is used in unhealthy noses whatever is the matter when, in the majority of cases, surgical interference is the proper treatment. A placebo is sometimes a useful thing, but nasal lavage is a dangerous one. It is common to treat an ordinary cold by irrigation, usually with salt and water, and it is then especially likely to cause middle-ear inflammation. I have lately had three such cases in private practice in 48 hours, one of which just escaped with life after an extensive mastoid operation. In each one the solution was felt to enter the ear immediately before the onset of pain. A cold is an infective inflammation of the nasal lining membrane and such treatment is not only a danger to the ears, but violates the fundamental rules for the treatment of inflammation—namely, rest and heat. I am constantly hearing of this method of treatment for colds by the matrons in our schools. I wish to protest most strongly against it, but am afraid that nothing will stop it unless parents order that nasal lavage in any form should never be used by their children before they enter a school and if, in spite of this, it is done and evil results, an action for damages is brought against those responsible.

I am, Sir, yours faithfully,
Arthur H. Cheatle.

Harley-street, W., Nov. 23rd, 1925.

POST-GRADUATE EDUCATION.

To the Editor of The Lancet.

Sir,—At the dinner of the Royal Society of Medicine on Thursday last the Minister of Health referred to the establishment of a post-graduate school in London which would attract general practitioners from the country and towns to learn from the leaders of the medical profession. I am in agreement as to the advantage such a school would possess for those fortunate enough to attend it. I cannot help feeling, however, what an advantage it would be if the leaders of the profession who have spent so much time dealing with the end-results of disease in our hospitals could in their turn go to the country practitioner and to the welfare medical officers of our big factories for a time and study the very first symptoms of diseases which, if unchecked, will ultimately bring their victims into the out-patient department, and finally into the in-patient department of the great hospitals. The worker suffers from these early symptoms for quite a time while still carrying on his daily task, and only goes off duty when he has used up the reserves which enabled him to carry on in spite of his disability.

If this form of interchange were associated with post-graduate teaching, the medical profession would benefit, and the public to an even greater extent. The present system of hospital staffing is not the one best calculated to assist in the progress of medical knowledge. The young physician takes on the care of out-patients, and when he is older and more experienced he takes on the care of beds in the wards which are filled with the end-results of disease. If the situations were reversed and the senior men had charge of the out-patient department they might prevent many cases passing on to the in-patient stage of diseases, and the number of beds which needed their experienced care because of the rare diseases would not be great. No very special knowledge is required to deal with cases of advanced disease which occupy so large a proportion of medical beds. In time the junior staff would be promoted to the out-patient department.

I am, Sir, yours faithfully,
Bruce Bruce-Porter.

Grosvenor-street, W., Nov. 23rd, 1925.

MYOMECTOMY AS THE TREATMENT OF ELECTION FOR UTERINE FIBROIDS.

To the Editor of The Lancet.

Sir,—I suppose the majority of gynæcological surgeons are in agreement with Mr. Victor Bonney in his teaching that the uterus during the child-bearing period should be conserved if possible, and that it is possible in many cases at least to conserve the organ when the seat of fibroid formation, to the extent indeed of rendering future pregnancy possible in some, he has shown. But that myomectomy is of service and should be done after the climacteric is another question. The uterus at this time is presumably of no further use, is liable to serious disease, and the value of conserving it, to say the least, is questionable. The incidence of malignant disease of the uterus in the general population may be small, and not much greater or not greater in women with than in those without fibroids, but the danger is always there. When we think of the mortality of Wertheim's operation, even in expert hands, and the number of recurrences after this operation, it seems to me that the conservation of the uterus, the seat of fibroids in post-climacteric life, is carrying the art of surgery too far. If prophylactic pan-hysterectomy for slight and suspicious lesions of the cervix in such period of life is justifiable, as I think it is, much more reasonable, it seems to me, is the removal of the whole uterus when the seat of fibroids in such period. In this respect, the slightly greater risk of pan-hysterectomy compared with sub-total comes up for consideration. With the advance of pelvic surgery it can hardly be believed that the mortality and morbidity of the former operation is not greatly less at present than it was fifteen years ago. The position requires reviewing. Personally, I think the sub-total operation to-day is too often performed.

But however gynæcologists may view this subsidiary question, few, I think, will sympathise with Mr. Bonney's teaching or accept the reason he gives for conserving the uterus, the seat of fibroids, in some elderly women. In his series of 120 cases of all ages, he had three deaths. Two of these deaths occurred in "elderly women" in whom the "object of conserving the uterus was . . . to ventrofix it and make it act as an artificial ligament to hold up a prolapsed vaginal vault." Mr. Victor Bonney knows, or should know, as well as anyone else, that the uterus cannot be made to serve the purpose of a ligament to hold up the vaginal vault. Many instances have been cited of the uterus having been used in this way, but with the return to active life the same result has always occurred. If the "prolapse" is not prevented by other means, with resumption of general activity, the uterus elongates or the part of the abdominal wall to which its fundus is attached is depressed, the prolapse returning and the state of the patient becoming worse than before. The uterus as a suspensory agent is of no service in the prevention of pudendal hernia. It can only be of service if it can be used to play the part of a pessary (or an intra-corporeal truss), as in the interposition operation—in which, however, if malignant disease be feared, the endometrium can be removed.

It is unfortunate that Mr. Bonney should thus weaken his otherwise excellent argument.

I am, Sir, yours faithfully,
R. H. Paramore, F.R.C.S. Eng.

Rugby, Nov. 21st, 1925.

THE TROPHOBLASTIC HYPOTHESIS OF CANCER.

To the Editor of THE LANCET.

SIR,—Prof. Blair Bell's adoption without acknowledgment of the unfruitful trophoblastic (or chorionic) hypothesis of the nature of cancer, first put forward more than 20 years ago (THE LANCET, 1902, i., 1758) by my former teacher, the late Dr. John Beard, cannot be allowed to pass without remark from me. From that paper, in which the theory was outlined, the penultimate sentence may be quoted :—

> If such a chorion the representative more or less complete of the asexual generation, when robbed of its embryo or when it fails to form such, can—and this is established—give origin to a malignant carcinomatous tumour the nature of cancer is clear.

The patronising attitude towards other workers which pervades Dr. Bell's whole lecture comes ill from one who, it is charitable to assume, is himself ignorant of the recent literature of the subject.

I am, Sir, yours faithfully,

J. A. MURRAY.

Imperial Cancer Research Fund, 8, Queen-square,
W.C. Nov. 25th, 1925.

TELLING THE TRUTH.

To the Editor of THE LANCET.

SIR,—Doctors, in the course of their professional duties, have to tell many falsehoods, and now and again a discussion arises as to the ethics of professional lying, or rather, lying by a professional healer. It is not often, however, that such a witty defence of the professional lie is made as that published by Dr. Boutarel in a recent number of *Paris Médical*. After recalling the famous controversy, celebrated by Pascal in *Les Provinciales*, between the Jansenists and the Jesuits on the subject of restrictions of thought, Dr. Boutarel reminds us that in actual fact we all practise such restrictions. You borrow 50*s*. from a friend, saying : "I will pay you back," but adding, in your own mind, "if I have any money." The Jansenists would call this hypocrisy, the Jesuits diplomacy. Or again a dealer in antiques lays his hand on a piece of furniture, declaring solemnly : "I guarantee that this is old," but he carefully avoids touching the bronze corner-pieces which have just been added. "Disgracefully underhand !" cry the Jansenists. "Merely skilful," protest the casuists.

In the medical profession such restrictions are everyday affairs. Morphine, administered to a hopeless case, is termed "serum." The pretty wife of a faithless husband is assured that her husband has become infected through drinking out of a dirty glass. A bullet wound in the head is called a cerebral hæmorrhage, and so the pious falsehoods go on. Some doctors try to solve the insoluble by refusing a diagnosis in certain cases, but this is no real solution. *Qui ne dit mot consent* and to withhold a diagnosis is equivalent in some cases to making an accusation. With regard to professional confidences, there is only one attitude to take, thinks Dr. Boutarel, and that is for the doctor to keep sacred all secrets confided to him, even if questioned in a court of law. Should a medico-legal expert be called and should his evidence prove the correct diagnosis, and thus show up the doctor in charge of the case, the latter ought to be exonerated from any blame. Life without falsehoods would be insupportable ; we lie daily through politeness, through laziness, through self-interest, so why should we not lie occasionally in the interests of a third person ?

It seems to me that many besides Dr. Boutarel have found that a few lies, in the shape of half-truths, will sometimes go a long way towards effecting a cure.

I am, Sir, yours faithfully,

Nov. 22nd, 1925. CROIX ROUGE.

Obituary.

SIR ROBERT CHARLES BROWN, F.R.C.P. LOND., F.R.C.S. ENG.

Sir Robert Charles Brown, a well-known physician of Preston, Lancs, died at his residence in Winckley-square, Preston, on Nov. 23rd at the age of 89. He was a son of Alderman Robert Brown, F.R.C.S., and was born in Preston, where he received his early education. He pursued his medical studies at King's College Hospital, London, and in Edinburgh and Dublin, qualifying L.S.A. and M.R.C.S. Eng. in 1858. Three years later he obtained the M.B. Lond., and in 1862 was admitted F.R.C.S. Eng. by examination. In 1908 he was admitted a Fellow of the Royal College of Physicians. Throughout his professional career he was closely associated with the Preston Infirmary since its opening in 1870, as medical officer in his younger days and as a generous benefactor to its material needs in later years, besides holding the post of consulting medical officer. It was in recognition of his services to that and other institutions that he was made an hon. freeman of the borough in 1910. From the first he was closely connected with the work of the Cambridge Committee for the Study of Special Diseases. He promoted it in various ways, by personal effort and enlisting the support of others, by installing a complete X ray apparatus, by providing the most efficient microphotographic microscope obtainable, and, above all, by founding a studentship for pathological research. For these services the University of Cambridge conferred on him the hon. degree of M.A. in May, 1912, and on the following day he formally opened the Research Hospital built on the Hills-road. Sir Robert Brown was three times president of the Lancashire and Cheshire branch of the British Medical Association, and was an esquire of the Order of St. John of Jerusalem. He was knighted in 1919.

JOHN JAMES BLAGDEN, M.R.C.S. ENG.

BY the death of Dr. Blagden, Chester has lost one of its leading surgeons. He studied at St. Bartholomew's Hospital, London, and at Cambridge, graduating B.A. Camb. in 1893, and qualifying M.R.C.S. and L.R.C.P. in 1896. After qualifying he was assistant house surgeon at the Taunton and Somerset Hospital and honorary surgeon at the Tavistock Cottage Hospital. He settled in Chester nearly 30 years ago, where he was assistant honorary surgeon at the Chester Royal Infirmary from 1909 to 1919, when he was elected honorary surgeon to this institution. He retired last May owing to ill-health. During the war he rendered valuable service in orthopædic surgery as surgeon in charge of this department in Chester. He was a past president of the Chester Medical Society and chairman of the Chester Division of the British Medical Association. He leaves a widow and one son, who was recently called to the Bar.

MEMORIAL COTS AT VINCENT-SQUARE HOSPITAL.—Last week Mr. J. Gomer Berry, the chairman, formally accepted more than 20 "memorial cots" which have been given to the Infants Hospital in Vincent-square, Westminster. The Prudential Assurance Co. has given six cots in "The Prudential Ward," together with the installation of the X ray room.

ENLARGEMENT OF LONDONDERRY INFIRMARY.—The Duchess of Abercorn has this week opened the new Poston wing of Londonderry City and County Infirmary. The wing is named after two brothers, the late Robert and John Poston, who provided a large proportion of the cost. It will hold 25 patients, which brings up the total number of beds to 100. Accommodation is also provided for a resident surgeon, two house surgeons, the matron, six sisters, and 19 staff and probationer nurses. The infirmary, which dates from 1789, was last enlarged 20 years ago.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

AT a recent meeting of the Section of Surgery held in the Royal College of Physicians of Ireland, with Mr. R. C. B. MAUNSELL, the President, in the chair, Mr. R. A. STONEY showed a woman of 30 who had suffered from all the clinical symptoms of exophthalmic goitre. In spite of rest in bed, sedatives, and Lugol's solution the pulse-rate, which at first fell, increased and the patient lost weight. Immediately before operation the basal metabolism was increased by 46 per cent. The patient was given rectal ether and the right lobe isthmus and lower half of the left lobe were removed. Three weeks after operation the basal metabolism had fallen to 27 per cent. below normal, the pulse had fallen and was steady. Tremors had almost entirely disappeared, exophthalmos had decreased, weight had increased, and the patient stated that she felt much better and was now eating and sleeping well.

Mr. H. STOKES said that he had operated on a good many cases of patients with exophthalmic goitre, and the results on the whole had been distinctly good. He had found that iodine acted very well; recently he had a patient whom he had put on iodine, and her pulse-rate had come down, but immediately he stopped the iodine her pulse went up again. He did not do lobectomy, but he took out a large portion of the centre of each lobe, after doing a preliminary ligature of the upper lobe. He had done about four or five such operations a year for the last few years. He had altogether operated on about 35 patients, and only two had died. One, a very bad case, did not recover from the anæsthetic, and the other died from septic pneumonia.

Dr. G. E. NESBITT said that it was sometimes stated that physicians were reluctant to give their patients with exophthalmic goitre over for operation. He did not think this was true, but they wanted more proof that operation was the best method of dealing with these cases. No mention had been made of the treatment by X rays, and he thought that most people if they got exophthalmic goitre would prefer to be treated in that way first. Good results certainly were often obtained by X ray treatment. At present he had a patient in hospital, a girl of 18, who on admission was practically moribund, and for some time it was impossible to do anything for her. When he managed to get her weight it was only 3 st. 8 lb. Later she had a course of X rays, and during this time she put on 9 lb. in weight. He now wondered whether she should have a further course of X rays or whether she should be operated on. She would not have stood an operation before, and he doubted if she would stand one now. He thought that it was very hard to judge how much thyroid should be removed in these cases.

Mr. H. MEADE said that he thought surgeons seldom get patients of exophthalmic goitre handed over to them early enough and so they really did not get a chance with them. If good results were to be obtained by operation it was necessary to operate early.

Mr. L. G. GUNN said that he saw a good many cases of goitre, and he would divide them into two classes, mild cases and really very severe cases. He had operated on 14 severe cases and two had died directly as a result of the operation. Of the other 12, two had shown a definite return of exophthalmic symptoms, one after five years and the other after eight years. He thought that probably he had not taken a sufficient amount of thyroid gland away; but he felt that even after surgery there was likely to be a certain amount of recurrence. A great deal depended on the patients; if a patient had only to do light work, or no work at all, then medical treatment and X rays might be given; but if the patient had to do hard work, then he would advise operation. He had seen a good many cases greatly improved after medical treatment, but very few of these had been fit to go back fairly soon to work, while after operation they were fit to work in quite a short time. Of course, sometimes quite a simple operation was followed by a very severe reaction, and even death.

THE IMPERIAL NURSING SERVICES.

THE name of the late Queen Alexandra is intimately associated with all the official nursing services of the Army, the Navy, and of India.

The committees of *Queen Alexandra's Imperial Military Nursing Service* and of the Territorial Army Nursing Service conjointly make up the *Queen Alexandra's Army Nursing Board*. This Board, formed in 1902, was constituted as follows:—

President: H.M. Queen Alexandra.

Vice-President: The Dowager Countess of Airlie, G.B.E.

Chairman: The Director-General, Army Medical Services.

Two members nominated by the President and holding office for three years.

Two members of the Advisory Board, Army Medical Service, one of whom is a civilian.

Four matrons of large civil hospitals with medical schools.

Matron-in-chief, Q.A.I.M.N.S.

Joint Secretaries: Matron-in-chief, T.A.N.S.; Principal Matron, Q.A.I.M.N.S.

The Board meets twice yearly, and is responsible for advising the Army Council in all matters affecting the Army Nursing Services. The Q.A.I.M.N.S. Committee meets monthly to deal with applications of candidates for the service, promotions, retirements, and reports of hospitals. The Board has not merely to advise in regard to the nursing of the soldier in peace, but has also to initiate schemes for the rapid and extensive expansion of the service on the outbreak of war. To meet these requirements a reserve of nurses has been formed. The T.A.N.S. Committee meets twice a year on the same day as the Board.

By Order in Council of March 6th, 1902, authority was obtained to designate the staff of nursing sisters in naval hospitals by the title of *Queen Alexandra's Royal Naval Nursing Service*. The present staff comprises three head sisters, eight superintending sisters, and 61 nursing sisters. Members serve at R.N. Hospitals at Haslar, Chatham, Plymouth, Portland, and Queensferry; R.N. Sick Quarters at Dartmouth and Shotley; and R.N. Hospitals abroad at Malta and Hong-Kong.

The *Queen Alexandra's Military Nursing Service for India* consists of a chief lady superintendent, a number of lady superintendents, and nursing sisters to the number required by the strength of British troops in India. The chief lady superintendent is an administrative official; the other members undertake the nursing of sick and wounded British soldiers, besides instructing the male nursing orderlies in nursing duties and supervising their work. The Nursing Service also supervise the management of the family hospitals, which exist for the care of the families of British officers and soldiers. A proposal is under consideration to amalgamate the Nursing Service for India with the Imperial Military Nursing Service, and to arrange for members of the combined service to proceed to India in the course of their career for a tour of duty with British troops, on the same system as that in force with regard to the Royal Army Medical Corps.

QUEEN ALEXANDRA'S LAST MESSAGE.—The annual meeting of Queen Victoria's Jubilee Institute for Nurses was held at St. James's Palace on Wednesday in last week. The Duke of Portland, who presided, read a message which he had received from Queen Alexandra wishing prosperity to the Institute, and expressing the hope that the financial outlook might continue to improve, and her thanks to all the workers for "the good cause which is so near to my heart." Mr. Neville Chamberlain, the Minister of Health, delivered an address in which he said that much of the money and work spent on medical services would be thrown away if it were not for the work of the district nurses.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

New Public Health Bill.

On Monday, Nov. 23rd, the House considered the Rating and Valuation Bill as amended in Standing Committee, and Mr. Barker moved a new clause to exempt underground sewers from rating. Mr. Neville Chamberlain said that he had much sympathy with the proposal to exempt from rating not only sewers, but also such things as pipes which conveyed water from a reservoir to a town many miles distant and which passed through the areas of different local authorities. While he could give no guarantee as to future legislation, he hoped next year it might be possible to introduce a Bill to amend the Public Health Acts and if so that might be a suitable opportunity to deal with the matter. The clause was negatived.

HOUSE OF COMMONS.

Wednesday, Nov. 18th.

Approved Societies and Dental Benefit.

Mr. Forrest asked the Minister of Health what were the types of benefits now being given by the approved societies, and especially how many of them provided dental benefit; and whether he was in a position to make specific recommendations to the societies as to the directions in which benefits should be given.—Mr. N. Chamberlain replied: The additional benefits which are now being provided by approved societies out of surpluses disclosed on a valuation include, in addition to increases of the standard rates of sickness, disablement and maternity benefits, dental benefit, ophthalmic benefit, treatment in convalescent homes, the provision of medical and surgical appliances, and payments to hospitals and for nursing. Dental benefit has already been adopted in England by 794 societies and 2662 branches, and these numbers will no doubt be increased when the whole of the schemes following the second valuation have been formulated. As regards the last part of the question it rests with each society to consider which of the additional benefits are best suited to the needs of its members, but any scheme adopted requires the sanction of the department before it can be brought into operation, and where a society's proposals are thought for any reason to be inappropriate recommendations for amendment are made to the society.

Reduction of Insurance Contributions.

Mr. Forrest asked the Minister of Health whether he was now in a position to make a definite statement as to the intentions of the Government regarding the proposal to reduce contributions under the National Health Insurance Act.—Mr. N. Chamberlain replied: The answer is in the negative. It will be remembered that a Royal Commission is at present investigating the National Health Insurance scheme.

British Social Hygiene Council.

Major-General Sir John Davidson asked the Minister of Health what was the amount of the grant given to the British Social Hygiene Council and what, if any, stipulations were made as to the manner in which it was expended.—Mr. N. Chamberlain replied: The amount of the grant paid to date during the current financial year is £5500. The grant is expended on the carrying out of a programme of educational work, the details of which have received the prior approval of my department.

Preventives for Venereal Disease.

Major-General Sir John Davidson asked the Minister of Health whether he was in a position yet to give any reply to the joint deputation of the National Council for Combating Venereal Disease and the Society for the Prevention of Venereal Disease received by him on March 5th, 1925, in relation to the alteration of the law regarding the sale by chemists of preventives for venereal disease.—Mr. N. Chamberlain replied: I would refer my hon. and gallant friend to the answer which I gave to his question of June 22nd. I am still awaiting a reply to the letter which I addressed to the two societies on May 15th last.

Geneva Opium Convention.

Mr. Campbell asked the Secretary of State for Foreign Affairs which of the powers had ratified the Opium Convention, signed at Geneva on Feb. 19th, 1925.—Mr. Chamberlain replied: No information has yet been received as to which powers, if any, have ratified the Convention. The period for signature only closed on Sept. 30th last.

Vaccination and Small-pox.

Mr. Groves asked the Minister of Health if he would give statistics, with such approximate accuracy as the available information permitted, showing the proportion of the population then living which had been vaccinated at public expense in each of the years 1852, 1853, 1854, 1871, 1872, 1882, 1883, 1884, 1902, 1903, 1904, 1922, 1923, and 1924, if figures for that year were available, and the number of deaths from small-pox in each year; and the number of cases of supposed small-pox notified in each year beginning with 1892.—Mr. N. Chamberlain replied: There are no statistics available showing what proportion of the population living in the years mentioned in the question had been vaccinated at public expense, but I would refer the hon. member to the figures given him on April 7th last as to the percentages of vaccinations to births, and the numbers of deaths from small-pox during each of the years 1872 to 1924. The deaths from small-pox during the years 1852, 1853, 1854 and 1871 numbered 7320, 3151, 2808, and 23,062 respectively. As regards the last part of the question particulars of the numbers of cases of small-pox notified are available only for the years 1911 onward, and the figures (excluding port sanitary cases) are as follows:—

1911	265	1916	135	1921	311
1912	111	1917	6	1922	967
1913	90	1918	51	1923	2477
1914	57	1919	262	1924	3757
1915	78	1920	243		

It should be understood that these figures represent not notifications only. They have not been subjected to the corrections and additions set forth in the small-pox section of the annual reports of the Chief Medical Officer of the Ministry of Health.

Panel Doctors and Medical Certificates.

Mr. Walter Baker asked the Minister of Health whether he was aware of the practice of panel doctors to charge for a medical certificate for a patient's private employer, such certificate being additional to that required by the patient's approved society; whether any provision was made under the Health Insurance Act for providing such additional certificate free of charge; and, if not, whether he would take steps to secure that some such provision is made.—Sir Kingsley Wood (Parliamentary Secretary to the Ministry of Health) replied: My right hon. friend is aware that such a charge is sometimes made, though he has no information as to the extent to which the practice prevails. There is no statutory provision for the issue of certificates other than those required for National Health Insurance purposes and the hon. Member's proposal would require legislation.

Registration of Nursing Homes.

Mr. Gerald Hurst asked the Minister of Health whether he would now appoint a Committee to inquire into the desirability of legislation for the purpose of registering and supervising nursing homes.—Sir Kingsley Wood replied: In view of the present pressure of work and the difficulty of completing the inquiry before the end of the session it is not proposed to proceed with the appointment of a Select Committee this year, but steps will be taken to set up the Committee at the earliest practicable date next session.

Transference of Pensions Work from Scotland to London.

Dr. Shiels asked the Minister of Pensions what was the exact nature and extent of the work formerly done in Scotland, and now transferred to the Ministry of Pensions in London; was it intended to carry this process further within any definite period, and would the Scottish Advisory Council be consulted before any such steps are taken in the future.—Mr. Thomas Kennedy asked the Minister of Pensions if he was aware of the very strong feeling aroused in Scotland by the intimation that the Scottish Regional Office of the Ministry of Pensions was to be closed, and the work now being done there transferred to London; and if he would concede the request of the Scottish Advisory Council that the decision to transfer the widows and dependants section to London should be delayed pending Parliamentary discussion of this proposal.—Lieut.-Colonel G. F. Stanley replied: The work transferred from the Ministry's sub-office in Edinburgh to London consisted in the handling of claims of widows and dependants referred from the area offices. The work involved formed only a small section of the work of the Regional Office in Edinburgh, as may be gauged by the fact that it occupied the time of only 22 clerks, or less than one-tenth of the Regional Office staff. The transfer of this small branch of the work, which has now been carried out, was directed by my right hon. friend for technical reasons. My right hon. friend must hold himself free, in the exercise of his responsibility as a minister, to make any change in administrative routine which he is satisfied will make for efficiency of administration consistently with the interests of pensioners. The re-centralisation of the entire work of the Regional Office in Edinburgh is, as already publicly stated, not in issue at the present moment, though the time is probably not far distant, according to present indications, when the decline in the volume of the Ministry's work will render the retention of a sub-office unjustifiable in Edinburgh, as has already been found to be the case in other parts of the United Kingdom. When, however, the time arrives for a decision to be taken, it is my right hon. friend's intention to give his Scottish Advisory Council an opportunity of expressing their views.

THURSDAY, NOV. 19TH.

Supply of Artificial Limbs.

Mr. **GEORGE HARVEY** asked the Minister of Pensions if he was aware that the number of contractors to the Ministry for artificial limbs had been recently reduced from 14 to 2, and special concessions made to those favoured 2 firms to the unreasonable detriment of the other 12; and was he prepared to reconsider his decision and meet a deputation from the remaining 12, whose businesses had consequently been necessarily seriously curtailed, if not actually closed down.—Mr. **ROBERT MORRISON** asked the Minister of Pensions why the number of firms supplying artificial limbs to disabled ex-Service men through the Ministry of Pensions had recently been limited to two.—Major **TRYON** replied: In consequence of refusal by the firms of limb makers hitherto under contract with the Ministry for the supply of artificial metal legs to continue to renew their contracts, except on terms which would have involved a greatly increased charge on public funds, I appointed a committee of inquiry, presided over by Sir Godfrey Collins, and including Major Cohen and other representatives of disabled officers and men, to investigate the whole position with regard to the supply and repair of this type of limb. Following the committee's report and recommendations, the number of firms with whom contracts were made for the supply and repair of artificial metal legs has been restricted to two. I have also received a deputation representing 10 of the 12 firms of limb makers who no longer hold contracts for the supply and repair of these limbs and have informed them that the matter cannot be reconsidered. The position is that certain firms had formed a combination against the Government, but, thanks to the committee, a cheaper supply of artificial limbs has been obtained.

In reply to further questions Major Tryon said that the limbs supplied were of first-rate quality. The House would wish him to express the debt of ex-Service men and of the country generally to the committee.

Bakers' Dermatitis.

Mr. **FORREST** asked the Home Secretary whether any legislation was contemplated in connexion with the spread of dermatitis among bakers, in view of the fact that operatives suffering from this disease were at present permitted to go on working with consequent risk to the consuming public.—Sir W. **JOYNSON-HICKS** replied: No legislation is contemplated, but the question of issuing an order requiring the occupiers to adopt special precautionary measures is now under consideration.

Colonel **DAY** asked the Minister of Health if he was aware that improvers, such as boric acid, used by bakers to improve bread, resulted in dermatitis; and whether, in view of this danger to public health, he would consider the advisability of making an order prohibiting the use of such improvers by bakers.—Mr. N. **CHAMBERLAIN** replied: The effect on the health of the consumer of the treatment of flour with "improvers" and other chemical substances is at present being investigated by a departmental committee, and pending their report I could not entertain a proposal to make restrictive regulations. I may add that so far as I am aware boric acid is never added to flour.

Increase in the Population.

Mr. **SANDEMAN** asked the Minister of Health what was the estimated increase of population in Great Britain since the last Census returns.—Mr. N. **CHAMBERLAIN** replied: The estimated increase of population in England and Wales from the date of the last Census in 1921 to the middle of 1925 is 1,003,000.

Smoke Abatement.

Sir **WALTER DE FRECE** asked the Minister of Health whether he proposed to introduce a Bill dealing with smoke abatement; and, if so, whether he could indicate when this would be.—Mr. N. **CHAMBERLAIN** replied: I hope to introduce a Bill on this subject next session.

The Case of Prince Ahmed.

Lieut.-Commander **KENWORTHY** asked the Minister of Health whether, when Prince Ahmed Seif-ed-Din escaped from Ticehurst asylum, detectives attached to the special branch of Scotland Yard were sent to France to effect his arrest; if he was aware that the prince had been confined in asylums in England since 1902 and that repeated efforts to have the patient examined by independent specialists had been refused; and whether he would make a statement on the subject, in view of the fact that the prince had established his sanity since leaving this country.—Mr. N. **CHAMBERLAIN** replied: I would ask the hon. and gallant Member to address the first part of his question to the Home Secretary. As regards the second part, I am informed that Prince Ahmed was confined in an asylum in this country from July, 1900, to September, 1925. During that period he has been frequently seen by medical and legal commissioners of the Board of Control. Within a year of his original detention a special visit was paid to him by a medical commissioner; and a similar visit was paid as recently as July, 1924, when the commissioner was satisfied that the prince was insane and properly detained. In September, 1924, the patient was examined by three independent specialists, two being eminent alienists of this country and one a specialist from Zurich. They also expressed the view that the prince was definitely of unsound mind. A further application for an examination by independent specialists was made to the Board in the same month, but was declined because it was considered that another medical inquisition at such a short interval might be detrimental to the patient's health. In regard to the third part of the question, I have no information relative to the statement that the prince has established his sanity since leaving the country; but I am advised that, judged by the standard of conduct recognised in this country, he was undoubtedly insane at the time of his escape.

Patients in Poor-law Hospitals.

Mr. **NAYLOR** asked the Minister of Health whether he would consider the advisability of introducing a Bill to remove the anomaly existing under the provisions of Section 46 (1) (*b*) of the Local Government Act, 1894, whereby members of boards of guardians and borough councils were disqualified from office owing to their entering or a member of their family entering a Poor-law hospital, notwithstanding that the full cost of maintenance was paid for the whole period of chargeability.—Mr. N. **CHAMBERLAIN** replied: I cannot see my way to introduce a Bill for this purpose at the present time.

Instruction in Birth Control.

Mr. **BASIL PETO** asked the Minister of Health whether he had received requests from electors in London and the provinces asking that advice and instruction on birth control should be given at maternity centres to married women on the recommendation of medical men; and whether these requests included many from medical officers of health and other persons in authority.—Mr. N. **CHAMBERLAIN** replied: The answer to the first part of the question is in the affirmative. As regards the second part I have no record of having received such a request from any medical officer of health, but a few have been received from magistrates, doctors, teachers, and other responsible persons.

Free Clinics for Cancer Treatment.

Mr. **FORREST** asked the Minister of Health whether, in connexion with the prevention of cancer, his attention had been drawn to the establishment in America of free clinics whereat all persons with suspicious growths were able to attend, whether he had ascertained if medical opinion in this country was in favour of the inauguration of such centres here; and, if so, whether he could give any estimate of what the cost would be.—Mr. N. **CHAMBERLAIN** replied: I am aware that certain free clinics have been established in the United States for the purpose indicated by the hon. Member. As regards this country, there are numerous out-patient departments of general hospitals and other medical institutions (specialised for the treatment of cancer or otherwise), at which persons who suspect that they are suffering from the early stages of cancer can receive gratuitous diagnosis, advice and treatment. In July, 1923, the Departmental Committee on Cancer, appointed by one of my predecessors, made certain recommendations as to the way in which local facilities for early diagnosis and treatment of this disease might be improved by local action. These recommendations were embodied in a circular issued by my department to local authorities on August 14th, 1923,[1] and are, I understand, now being followed in several of the larger cities.

Bethnal Green Medical Officer.

Lieut.-Colonel Sir **FREDERICK HALL** asked the Minister of Health whether, seeing that the Bethnal Green Metropolitan Borough Council recently approved a proposal for the appointment of a medical officer of health at a salary of £800, rising to £900 a year, and that his department intervened and expressed the view that the commencing salary should be not less than £1000, and in view of the recognised need for public economy and the fact that the salary offered by the borough council was considerably more than the income earned by a number of able, highly-trained general practitioners, he would state what were the general principles which had actuated the Ministry in taking this line.—Mr. N. Chamberlain replied: The salary first proposed by the borough council was considerably below the standard arrived at as appropriate to such an area after lengthy discussions between representatives of the Ministry of Health and of the British Medical Association and Society of Medical Officers of Health, with the assistance of advice from gentlemen of standing in the field of local government. In the circumstances I felt it impossible to approve the proposal of the authority and have sanctioned a temporary appointment.

---

[1] THE LANCET, 1923, ii. p. 479.

Treatment of Encephalitis Lethargica.

Captain Hudson asked the Minister of Pensions how many ex-Service men were now in the Star and Garter Home for Disabled Soldiers and Sailors suffering from encephalitis lethargica; how many were receiving pensions on account of this disease; and how many wives of such men were receiving allowances.—Major G. C. Tryon replied: This institution is not under my control, and I am not therefore in a position to furnish the desired information, except as regards those cases for whose treatment in the institution my department is responsible. Three such cases suffering from the disease referred to are being maintained in the home at the cost of the Ministry. In each case the usual treatment allowances are being paid in lieu of pension.

Contamination of Fish.

Captain Fairfax asked the Minister of Health whether, in view of the fact that fish is moister than meat, and, for that reason, more liable to contamination and risk by and from flies and dust, he had considered or would consider applying to fish the provisions of the Public Health (Meat) Regulations, 1924.—Mr. N. Chamberlain replied: That part of the meat regulations dealing with inspection at the time of slaughter would obviously be inapplicable to fish. The conditions under which fish and other foods are stored or sold are now governed by Section 72 of the Public Health Act, 1925, which applies to fish (amongst other foods) the important provisions of the regulations dealing with the conditions under which meat is stored or sold in shops.

Monday, Nov. 23rd.

Indian Medical Service.

Mr. David Grenfell asked the Under Secretary of State for India whether the recommendations of the Lee Commission with regard to the substitution of the Indian Medical Service by the Civil Medical Service had been given effect to.—Earl Winterton replied: The recommendations of the Lee Report as to the constitution of Provincial Civil Medical Services have been accepted in principle, subject to the need for maintaining for army requirements a reserve of medical officers in civil employ, and for providing medical attendance by British doctors for British members of the Services. It has been decided to maintain the Indian Medical Service in substantially its present form to meet army requirements, and the Government of India are now considering how best to adapt the civil branch of the service to the general scheme of medical reorganisation.

Opium Conditions in India.

Mr. Cecil Wilson asked the Under Secretary of State for India whether there was any intention on the part of the Government to have an official inquiry into opium conditions generally in India; and, if so, whether he could give this House any information as to the nature and scope of the inquiry.—Earl Winterton replied: About the beginning of this year the Government of India addressed local governments, drawing attention to some prima facie evidence of abuses of opium in various directions, and asked them to examine the question and to consider with the Government of India by what kind of special inquiry or committee the problem should be dealt with if the local governments come to the conclusion that the evidence makes it desirable to review the conclusions of the Royal Commission of 1893. In September last the Government of India stated that they were still awaiting the replies of local governments.

The Government and the Amani Institute.

Mr. Ramsden asked the Secretary of State for the Colonies the policy of the Government with regard to the Amani Institute.—Mr. Amery replied: I am glad to be able to say that the governments of the East African territories are prepared to grant sufficient funds to enable the Institute to be reopened. The necessary capital expenditure in this connexion can be found from the proposed guaranteed loan for which a Bill will in due course be laid before Parliament. H.M. Government are fully alive to the importance of Amani for the future development of East Africa.

Yaws in Kenya Colony.

Mr. Herbert Williams asked the Secretary of State for the Colonies the total number of cases of yaws in Kenya Colony last year; and how many of these received adequate medical treatment.—Mr. Amery replied: 29,402 cases of yaws were treated at Government hospitals and dispensaries in Kenya during the year 1924; and, in addition, 16,125 cases were treated by Government medical officers while on tour in their districts, either at out-dispensaries or otherwise. I fear it is impossible to estimate the number of cases which did not come to the notice of medical officers.

Replying to a supplementary question by Lieut.-Colonel Fremantle as to whether the Amani Institute was investigating this disease, Mr. Amery said the Institute was established for the purpose of research in connexion with plants and agriculture, but he was very anxious to promote research in health questions as well.

Medical Men in Kenya.

Mr. Herbert Williams asked the Secretary of State for the Colonies the number of qualified medical men in the public service and in private practice in Kenya Colony.—Mr. Amery replied: According to a return published on Jan. 21st last, there were 76 registered medical practitioners resident in Kenya, of whom 32 were European Government medical officers.

Machinery Accidents.

Mr. Walter Baker asked the Home Secretary whether, having regard to the high total of deaths due to transmission machinery, it was proposed to introduce fresh legislation rendering owners or persons responsible for the machinery liable to imprisonment in the case of avoidable accidents.—Sir W. Joynson-Hicks replied: In cases where an accident is due to neglect of the occupier to comply with the requirements of the law, the occupier is liable to a maximum penalty of £100, but I find that this maximum is not often imposed, and I doubt whether a power to sentence to imprisonment would be of much practical use. Successful proceedings for failure to fence transmission machinery have been recently taken in a number of cases and important decisions as to the liability of occupiers have been obtained from the High Court. Special steps have also been taken to instruct occupiers by the issue of a Safety pamphlet on the subject, and I am hopeful that these measures may have the desired effect.

Pensioners and the Spahlinger Treatment.

Mr. Vernon Davies asked the Minister of Pensions whether the information available in his department regarding the Spahlinger treatment was yet sufficient to justify him in arranging for the provision of this form of treatment for pensioners suffering from tuberculosis.—Lieut.-Colonel G. F. Stanley (Parliamentary Secretary to the Ministry of Pensions) replied: No Sir. I would refer the hon. Member to the reply I gave on July 28th last. The matter is one primarily for the Ministry of Health. My right hon. friend understands that the case must still, for the present, be considered "not proven."

Evidence by Former Lunacy Patients.

Sir Charles Oman asked the Minister of Health whether any further evidence from former inmates of asylums was to be taken by the Royal Commission on Lunacy; and whether requests for permission to give such further evidence had been received by that Commission during the last few months and refused.—Mr. N. Chamberlain replied: I understand that the Royal Commission, having heard oral evidence from 13 former inmates of asylums and considered a large number of written statements, do not propose to take further evidence of this nature. During the last six months eight applications have been received from former inmates desiring to give oral evidence; but the Commissioners have been unable to comply with these requests.

Tuesday, Nov. 24th.

Alterations in Pensions Administration.

Mr. Robinson asked the Minister of Pensions what were the names and salaries of the regional directors in the Ministry of Pensions; how many, if any, were on part time; how many had received an intimation that their services might at an early date be dispensed with; and whether his department had under consideration such reorganisation of the administration as would involve the closing of all regions by June, 1926, and the centralisation of administrative work in the Ministry headquarters in London.—Lieut.-Colonel C. F. Stanley replied: On the completion of the recent realisation of the Midlands region on the 5th proximo there will remain only two regions, Northern, with headquarters at Newcastle-on-Tyne, and Scotland, with headquarters at Edinburgh. In the Northern region the duties of regional director have for many months past been combined with those of the Commissioner of Medical Services without increase in emoluments. In the Scotland region the regional director is at present required to give part-time service only and receives a salary of £600 per annum. His services cease at the end of next month, and thereafter the duties will be combined with those of the Commissioner of Medical Services without increase in that officer's emoluments. Recentralisation is the policy of the present Government, as it was of the last, and arrangements are already in contemplation for closing the headquarters of the Northern region early in 1926. No decision has yet been taken on the question of the recentralisation of the Scotland region, but, as I indicated on Nov. 18th, the time is not far distant, according to present indications, when the decline in the volume of the Ministry's work will render the retention of separate regional headquarters in Edinburgh unjustifiable.

Health of Merchant Seamen.

Mr. BENJAMIN SMITH asked the President of the Board of Trade whether he would arrange for an annual report to be issued regarding the health of merchant seamen, giving a scientific analysis of diseases in the statistics published in the Return of the Shipping Casualties to and Deaths on Vessels Registered in the United Kingdom; give information as to the total number of men serving amongst whom the deaths occurred; and, in view of the apparent absence of medical advisers in the department, would he consider whether the health of seamen was a responsibility which might with advantage be transferred to the Ministry of Health.—Sir P. CUNLIFFE-LISTER replied: I will consider whether the statistics for which the hon. Member now asks can be prepared, but I would call his attention to the replies given him on March 3rd last, of which I am sending him copies.

Tests for Motor Drivers.

Sir FRANK SANDERSON asked the Minister of Transport if he would introduce legislation making the granting of licences to automobile drivers conditional upon their passing a recognised test in driving.—Colonel WILFRID ASHLEY replied: As I have stated on previous occasions, I am disposed to agree with the conclusion arrived at by the Departmental Committee on the Taxation and Regulation of Road Vehicles, as stated in their second interim report, that any advantages which at first sight might appear likely to result from the institution of tests on the lines indicated would be outweighed by the expense, difficulties, and disadvantages inseparable from any such system.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the undermentioned subjects:—

Surgery.—T. M. Beattie, Leeds; N. Cohen, Guy's Hosp.; S. E. Henty, King's Coll. Hosp.; M. Hook, Boston, U.S.A.; B. Horwitz, Guy's Hosp.; J. M. F. Whitby, St. Thomas's Hosp.; and D. Winstanley, Liverpool.

Medicine.—V. G. Crowley, Sydney and St. George's Hosp.; N. C. Ghose, Middlesex Hosp.; B. D. Jain, Charing Cross Hosp.; E. Kessel, Kharkov and Westminster Hosp.; and E. W. D. Long and J. Mindess, London Hosp.

Forensic Medicine.—M. Bannounah, A. M. El-Mishad, and C. L. Froehlich, Guy's Hosp.; M. Hook, Boston, U.S.A.; J. Mindess, London Hosp.; S. R. G. Pimm, Guy's Hosp.; L. A. Rostant, St. Thomas's Hosp.; and F. Widlake, Guy's Hosp.

Midwifery.—C. L. Froehlich, Guy's Hosp.; E. W. Hayward, Cambridge and London Hosp.; S. E. Henty, King's Coll. Hosp.; F. G. Martin, Charing Cross Hosp.; H. A. Sack, Middlesex Hosp.; and F. Widlake, Guy's Hosp.

The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery: C. L. Froehlich, M. Hook, F. G. Martin, and D. Winstanley.

UNIVERSITY OF LONDON LECTURES.—A course of five lectures on the Physiological and Pathological Activities and Functions of Bacteria will be given by Dr. F. W. Twort (Superintendent of the Brown Institution) in the Theatre of the Royal College of Surgeons (Lincoln's Inn-fields, W.C.) on Dec. 7th, 8th, 10th, 11th, and 14th, at 4 P.M.—A course of two lectures on the Efficiency of the Heart and its Measurement will be given by Prof. Yandell Henderson (Professor of Applied Physiology in Yale University) in the Physiology Theatre, University College, London (Gower-street, W.C.), on Monday and Tuesday, Nov. 30th and Dec. 1st, at 4.30 P.M. At the first lecture the chair will be taken by Prof. E. H. Starling, F.R.S. Admission to these lectures is free, without ticket.

Charing Cross Hospital Medical School.—The Huxley Lecture on Recent Advances in Science, in their Relation to Practical Medicine, will be delivered by Sir Oliver Lodge, D.Sc., F.R.S., on Thursday, Dec. 3rd, at 3 P.M., in the Out-patients' Hall of the hospital.

UNIVERSITY OF CAMBRIDGE: *Chair of Physiology.*—The election of a successor to the late Prof. J. N. Langley will take place in December. Candidates are requested to communicate with the Vice-Chancellor not later than Dec. 14th.

UNIVERSITY OF MANCHESTER.—The Court of Governors have appointed Mr. Walter Hamilton Moberley, M.A., D.S.O., at present Principal of University College of the South-West of England, at Exeter, to succeed Sir Henry Miers in September next as vice-chancellor.

NATIONAL HEALTH SOCIETY.—Dr. Robert Hutchison will deliver the Lady Priestley Memorial Lecture on Diet in Childhood and Adolescence on Thursday, Dec. 3rd, at 5 P.M., at 90, Buckingham Palace-road, S.W. (the Royal Sanitary Institute), Sir James Crichton-Browne, M.D., F.R.S., in the chair.

LONDON (ROYAL FREE HOSPITAL) SCHOOL OF MEDICINE FOR WOMEN.—A dramatic entertainment in aid of the Jubilee Endowment Appeal Fund will be given by the staff of the school on Dec. 11th at 8.30 P.M., and Dec. 12th at 3 P.M., and again at 8 P.M., at 8, Hunter-street, London, W.C. Tickets, 5*s.* and 2*s.* 6*d.*, may be obtained from Miss Bond, 8, Hunter-street, London, W.C. 1.

METROPOLITAN ASYLUMS BOARD: DIPLOMA IN PUBLIC HEALTH.—A course of lectures and demonstrations (three months) in hospital administration will be given at the North-Western Hospital, Lawn-road, Hampstead, N.W., by Dr. E. W. Goodall (medical superintendent), on Mondays and Thursdays, at 4.45 P.M., and alternate Saturdays at 10.30 A.M., beginning Thursday, Jan. 7th, 1926.

SOCIETY OF MEMBERS OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.—Sir John Bland-Sutton presided at the annual meeting of the Fellows and Members of this Society held at the College on Nov. 19th, when Dr. L. Haden Guest, M.P., moved the resolution which appeared in THE LANCET of Nov. 14th (p. 1043). It was, he said, inconceivable that in any other body than the College of Surgeons the same resolution should have been passed 36 times without notice being taken of it. All were agreed that the administration of the College had been and was being carried on in an exemplary manner, but the College owed a duty both to its members and to the public. The Council of the College had to deal with the conduct of examinations, the course of study, the choice of subjects, and the approval of schools and hospitals where instruction was given. The income of the College was derived to a large extent from its members, and he associated himself with those who advocated that the controlling body should be brought into closer touch with the general practitioner. Mr. F. Lawson Dodd, L.D.S., seconding the resolution, said that he represented the great unorganised mass of members who would like to have a closer union with the parent body. The result would be to give the College greater authority, a wider sanction, and more influence with the public. Dr. A. Haydon hoped it would be possible shortly to elect five members of the College on the Council, one for London and four for the provinces. Should this privilege not be granted he proposed the foundation of a new College of Surgeons with power to hold examinations and issue diplomas at lower fees than the present College. The resolution was carried with three dissentients. The President stated that the decision did not rest with him, but with the Council which was intending, before sending in the supplementary charter to the Privy Council, to give this matter very earnest consideration.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—On Monday, Nov. 30th, at 5.30 P.M., Mr. Herbert Tilley will lecture on Tuberculosis of the Larynx, in the lecture hall of the Medical Society of London, 11, Chandos-street, W. The lecture is free to all members of the medical profession. On Nov. 30th to Dec. 13th the Infants Hospital will hold a special course during the afternoons only, with the exception of Sunday, when a morning visit will take place to Thavies Inn, Holborn. Lectures and demonstrations will be given by Dr. Eric Pritchard and other members of the staff. Visits will be arranged to the Nursery Training School, Hampstead Garden Suburb, and the Home for Blind Babies, Chorley Wood. For the convenience of the general practitioner whose available time is limited, the Hampstead General Hospital will hold a 4.30 to 6 P.M. course from Dec. 7th to 19th, covering all branches of medicine, surgery, and the special departments. At the Hospital for Diseases of the Skin, Blackfriars, a course in dermatology will take place from Dec. 7th to 19th. Instruction will be given in the out-patient department, and venereal clinics will be held twice weekly. The following are the special courses for January:

Medicine, surgery, and the specialties at the Prince of Wales's General Hospital; cardiology at the National Hospital for Diseases of the Heart; diseases of children at the Queen's Hospital; infectious fevers at the North-Eastern Hospital; neurology at the West End Hospital for Nervous Diseases; and psychological medicine at the Bethlem Royal Hospital. A copy of each syllabus and the Fellowship general course programme will be forwarded on application to the Secretary to the Fellowship of Medicine, 1, Wimpole-street, London, W. 1.

Whitby's War Memorial Hospital.—Princess Mary on Nov. 18th opened a new cottage hospital at Whitby erected by the townspeople as a war memorial. For the new building—which has seven beds in the women's department, six in the men's ward, and three in the children's ward, besides four small wards with one bed in each—nearly £19,000 was raised to cover the cost of building and equipment. The operating block is the gift of Sir John Harrowing in memory of a son killed in the war.

Aimai Merwanji Chamarbagwala Free Ophthalmic Hospital.—The report of this institution for the year 1924 shows that it was started on a small scale in the year 1914 by two Bombay doctors. Its scope was enlarged in 1922 by the generosity of a Parsi gentleman after whose wife it is now named. In 1924 9200 new patients were treated. The number of cases operated on for cataract was 188, for glaucoma 26. The committee of management of this young institution consists of the two senior surgeons and the donor of the extension. It has an honorary staff of four and one house surgeon.

Manchester Cancer Committee.—The Manchester Cancer Committee has issued an appeal for £20,000 for the investigation into cancer during the next three years. The committee, which was formed at the instigation of the Minister of Health, numbers now 40 members, and consists of officially appointed representatives from the Public Health Committee, the University, the Manchester Royal Infirmary, the Christie Hospital, the Radium Institute, and other large hospitals in the city concerned with the problem of cancer in all its forms. The following scheme of investigation into cancer has been decided upon:—(1) Investigation of the blood and tissue changes in cancer cases by modern methods. (2) The collection of specimens from cancer cases for submission to a histologist for research purposes. (3) The establishment of a regular and complete system of record-keeping of cancer cases in all the city hospitals and in private practice. The occurrence of cancer amongst mule spinners gives the cotton manufacturing districts a special interest in any research work bearing on the investigation of the causes and increasing prevalence of cancer. The approved scheme will necessitate the appointment of full-time research workers and laboratory assistants and the provision of the necessary apparatus and clinical assistance. All money received will be expended entirely on investigations to be carried out in Manchester.

Queen Mary's Hospital for the East End, Stratford, E.—The twenty-second annual festival dinner of this hospital was held at the Hotel Victoria, Northumberland-avenue, on Nov. 23rd. Prince Henry, President of the hospital, had expressed the wish that the festival should not be postponed on account of the death of Queen Alexandra, and in his absence from the chair Lord Birkenhead presided over a large assembly of some 500 guests. The Chairman in giving the loyal toasts, briefly voiced the sympathy that all felt towards the Royal Family in their bereavement, and later in the evening made an eloquent appeal for funds on behalf of the hospital, for the maintenance of which £50.000 was required annually. Sir Leonard Lyle, chairman of the hospital, in response to Lord Birkenhead, said that there was a deficit of £7389 on the work of the past year, and that in future the expenses of the hospital would exceed the figure for 1924 by £9000 a year. Mr. H. Roper Barrett gave the toast of the honorary medical staff, the nursing staff, the voluntary workers, and officials of the hospital, to which Mr. A. J. Couzens and Major Raphael Jackson, the secretary, responded. In the course of his reply, Major Jackson announced that the sum of £5590 had already been received towards the total of £15,000, for which a special appeal was being made to free the hospital from debt and carry out a number of improvements. Sir Charles Wakefield gave the health of the Chairman of the Appeal Fund, Mr. H. Percy Shepherd, who himself headed the list of donors with a gift of £1000. The toast of the Visitors was given by Mr. W. A. Vernon, hon. treasurer of the hospital, and was acknowledged by the Mayor of West Ham. Sir Ernest Wild, K.C., proposed "The Chairman," to which Lord Birkenhead replied.

THE DEATH OF QUEEN ALEXANDRA.

Tribute of the General Medical Council.

At the first sitting of the General Medical Council, the President, Sir Donald MacAlister, paid a tribute to the late Queen Alexandra. The Council, he said, were meeting under the shadow of a national bereavement. "The death of the Queen-Mother Alexandra, revered and beloved by the whole nation, has made us all fellow-mourners with the Royal Family." Members rose in silence in homage to her memory.

Letter of Condolence from the British Medical Association.

The following letter, dated Nov. 24th, has been sent to Lord Stamfordham signed by the Chairman of Council of the British Medical Association:—

My Lord,—On behalf of the members of the British Medical Association throughout the Empire I respectfully beg leave to express to His Most Gracious Majesty the King, our Patron, Her Majesty the Queen, and the members of the Royal Family, the Association's heartfelt sympathy and profound sorrow at the death of Queen Alexandra, whose gracious thoughtfulness and unfailing devotion to the relief of suffering have endeared her to the profession. The Association joins with the whole Empire in mourning one so greatly beloved, and in expressing to His Majesty its loyalty and devotion.

I am, your Lordship's most obedient Servant,

(Sgd.) Robt. A. Bolam,
Chairman of Council.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, Dec. 1st.

ORTHOPÆDICS: at 8.30 P.M.
Discussion:
The Treatment of Fractures of the Forearm, Excluding Fractures of the Olecranon and those of the Lower End of the Radius of the Colles's Type.
Opener:
Mr. St.J. D. Buxton.
Mr. Bristow, Mr. Fairbank, Dr. James B. Mennell, Mr. Slesinger, and others will take part in the discussion.

PATHOLOGY: at 8.30 P.M.
Laboratory meeting at Guy's Hospital, S.E.
Communications:
Dr. G. W. Nicholson: Heterotopic Squamous-celled Carcinomata.
Dr. C. P. Symonds: Pathology of a case of Disseminated Sclerosis.
Mr. A. A. Osman: Treatment of Nephritis with Alkalies.
Prof. J. W. Eyre and Dr. Ali: *B. Ægypticus*, Rough and Smooth Colonies.
Mr. W. W. Payne: A Note on Various Carbohydrate Foods.
Demonstrations will be announced at the meeting.

Wednesday, Dec. 2nd.

SURGERY: at 8.30 P.M.
Clinical and Pathological Evening:
Cases and specimens will be shown.

Thursday, Dec. 3rd.

OBSTETRICS AND GYNÆCOLOGY: at 8 P.M.
Specimens:
Dr. Everard Williams:
(1) Fallopian Tube containing a Loose Fragment o Menstruating Endometrium associated with Endometrioma of the Ovaries.
(2) Uterus showing Multiple Polypi of the Cervix.
Short Communications:
Dr. D. J. Malan:
(1) Gliosarcoma in a Full-time Stillborn Fœtus.
(2) Ruptured Acute Pyosalpinx during the Third Month of Pregnancy.
Papers on Puerperal Sepsis:
(1) Dr. H. J. Phillips: Rational Treatment of Puerpera Infections.
(2) Dr. L. Colebrook: Some Laboratory Investigations i Connexion with Puerperal Sepsis.

Friday, Dec. 4th.

LARYNGOLOGY: at 5 P.M. (Cases at 4 P.M.)
Cases will be shown by Mr. H. Bell Tawse, Mr. A. J. Wright Mr. Douglas Guthrie, and others.

ANÆSTHETICS: at 8.30 P.M.
Paper:
Dr. M. S. Pembrey and Dr. F. E. Shipway: Apnœa Dyspnœa, and Cyanosis in Relation to Anæsthesia.

Saturday, Dec. 5th.

OTOLOGY: at 10.30 A.M. (Cases at 9.45 A.M.)

Cases and Specimens:

Dr. Albert A. Gray and Dr. Sarah B. Nelson: Pathological and Anatomical Conditions found in a Case of Deaf-mutism (illustrated by lantern slides).

Other cases and specimens will be shown.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, Nov. 30th, to Saturday, Dec. 5th.—Fellowship of Medicine lecture, Medical Society, 11, Chandos-st., W. Monday, 5.30 P.M., Mr. Herbert Tilley: Tuberculosis of Larynx.—Infants Hospital, Vincent-square, S.W. Special Course, Lectures, and Demonstrations every afternoon. Friday, "Round Table" Consultation. Saturday, Visits to Model Pasteurising Plant, Willesden, and Nursery Training School, Hampstead Garden Suburb.—Royal Waterloo Hospital, Waterloo-road, S.E. Special Course in Medicine, Surgery, and Gynæcology. Lectures, Demonstrations, &c., will be given in the Out-patient Department and Wards.—West End Hospital for Nervous Diseases, Welbeck-street, W. Lecture-demonstrations illustrated by cases daily at 5 P.M.—London Temperance Hospital, Hampstead-road, N.W. General Practitioners' Course, 4.30 to 6 P.M. (second week). All information as to fees, &c. from the Secretary.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Thursday, Dec. 3rd.—3 P.M., Mr. W. Ibbotson: Demonstration of Practical Tests for Vertigo. 4.15 P.M. (Clinical Meeting of the North-East London Clinical Society).

Daily: Clinics, Demonstrations, Wards, and Out-patient Department, General and Special Departments, Operations, &c.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C. 1.

Friday, Dec. 4th.—4 P.M., Mr. Archer Ryland: Musculature of the Vocal Cords.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL, Marylebone-road, N.W.

Thursday, Dec. 3rd.—5 P.M., Mr. L. C. Rivett: Antepartum Hæmorrhage.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-aquare, W.C.

Tuesday, Dec. 1st.—5 P.M., Dr. A. C. Roxburgh: Seborrhœa. Seborrhœic Dermatitis.

Thursday.—5 P.M., Dr. Haldin-Davis: Acne. Rosacea.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

Tuesday, Dec. 1st.—4.15 P.M., Mr. W. R. Douglas: Ureteral Calculi.

Friday.—4.15 P.M., Prof. J. Shaw Dunn: Recent Work on Renal Function.

JAMES MACKENZIE INSTITUTE FOR CLINICAL RESEARCH, St. Andrews.

Tuesday, Dec. 1st.—4 P.M., Mr. M. Ramsay: The Ocular Complications of Diabetes.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

Wednesday, Dec. 2nd.—4 P.M., Dr. A. Helen A. Boyle: The Attainment of Nervous and Mental Health.

Appointments.

Cohen, H., M.D. Liverp., has been appointed Lecturer in Practical Therapeutics in the University of Liverpool.

McFarland, B. L., M.B., Ch.B. Liverp., Honorary Assistant Orthopædic Surgeon to the Royal Liverpool Children's Hospital.

Vacancies.

For further information refer to the advertisement columns.

All Saints Hospital, Vauxhall Bridge-road, S.W.—Res. H.S. At rate of £200.

Birmingham and Midland Hospital for Skin and Urinary Diseases. Hon. Asst. P.

Birmingham Corporation Infectious Diseases Hospitals.—Sen. Asst. M.O. £500.

Birmingham, Queen's Hospital.—Anæsthetist, Obst. and Ophth. H.S. Also Cas. H.S. All at £70 to £100.

Bradford Royal Eye and Ear Hospital.—Res. H.S. £120.

Brighton, Hove, and Preston Dispensary, &c., 113, Queen's-road.—Hon. M.O.

Cairo, Memorial Ophthalmic Hospital, Giza.—Ophth. S. £E.1500.

Cambridge, Addenbrooke's Hospital.—H.S. £130.

Cardiff City Mental Hospital, Whitchurch, near Cardiff.—Locum Tenens. 7½ guineas weekly.

Cardiff, Welsh National School of Medicine.—Lecturer in Pathology. £750.

Chelsea Hospital for Women, Arthur-street, S.W.—Jun. H.S. At rate of £100.

Dumfries County Council.—Bacteriologist and Chemist. £650.

Essex County Council and U.D.C.'s of Grays Thurrock and Tilbury.—M.O.H. for U.D. of Grays Thurrock. £200. M.O.H. for U.D. of Tilbury. £200. And Asst. County M.O. for U.D. of Grays Thurrock, &c. £400.

Gloucestershire Royal Infirmary and Eye Institution.—Asst. H.S. At rate of £150.

Hampstead General and North-West London Hospital, Haverstock-hill, N.W.—H.S. and Cas. Surg. O. Each at rate of £100.

Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each at rate of £50.

Iraq Health Department.—Two M.O.'s. Rs.1200.

Kirkcaldy Hospital.—Res. M.O. At rate of £125.

Leeds Maternity Hospital.—University Tutor in Obstetrics and Res. M.O. £300.

Manchester, Ancoats Hospital.—H.S. At rate of £100.

North Middlesex Hospital, Edmonton, N.—Res. M.O. £200.

Nottingham General Hospital.—Res. Cas. O. At rate of £200.

Rainhill, County Mental Hospital.—Temp. Asst. M.O. £7 7s. weekly.

Royal Free Hospital, Gray's Inn-road, W.C.—Surg. Reg. £200. Also Med. and Gynæcological Reg. £100.

St. Andrew's Hospital, Dollis Hill, N.W.—Hon. Asst. P. and Hon. Asst. Gynæcologist.

Salford Royal Hospital.—Res. Surg. O. £200.

Singapore, College of Medicine.—Prof. of Biochemistry and Prof. of Biology. Each $850–$1000.

Stockport, County Borough.—M.O.H. £1200.

University College Hospital, Gower-street, W.C.—Med. Reg. £150. Also Hon. Dental S.

Winchester, Royal Hampshire County Hospital.—H.S. £150.

Windsor, King Edward VII. Hospital.—Jun. H.S. At rate of £100.

York County Hospital.—H.P. £150.

Births, Marriages, and Deaths.

BIRTHS.

Allerton.—On Nov. 12th, the wife of George Allerton, *M.C.*, M.R.C.S., Longridge-road, S.W., of a daughter.

Cowen.—On Nov. 17th, at Stafford House, Church-road, Sutton, Surrey, the wife of Dr. E. G. Huxley Cowen, of a son.

Noble.—On Nov. 17th, at Hill Crest, Husbands Bosworth, Leicestershire, the wife of Dr. Noble, of a daughter.

Stewart.—On Nov. 10th, at Woodside, Leavesden, Herts, the wife of R. M. Stewart, M.D., of a daughter.

Trace.—On Nov. 3rd, the wife of Laurence A. Trace, L.D.S. R.C.S., Kingsbridge, South Devon, of a daughter.

MARRIAGES.

Scott—Richards.—On Nov. 12th, at St. Stephen's Church, Bournemouth, Dr. Maitland Scott, to Ursula, only daughter of Mrs. Richards, of Sunbury, St. Stephen's-road, Bournemouth.

DEATHS.

Canton.—On Nov. 19th, at The Corner Cottage, Ventnor, Frederick Arthur Canton, L.D.S. R.C.S. Eng., of Ludham, Norfolk, aged 75.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

London County Council School Medical and Dental Service.—The extent to which the school medical and dental service of the L.C.C. is developing may be gathered from the fact that the Council has made financial provision for treatment, during the year 1926–27, of no less than 35,000 cases of refraction and eye diseases, 14,680 ear, nose, and throat cases, 1500 cases of ringworm, 70,600 cases of minor ailments, and roughly 126,000 dental cases. These figures represent an increase of nearly 11,000 over the number of cases authorised for treatment in the current year. The medical services of the Council have recently been under review. It has been found that the large increase in the number of cases treated by the Council's doctors is largely due to the fact that the hospitals are experiencing difficulties, and are being used to a less extent than formerly in the case of ailments for which the Council provides treatment. It is stated that the in-patient centres for the treatment of tonsils and adenoids have become so popular that many parents now refuse immediate appointments for treatment of their children as hospital out-patients, and prefer to wait until they can secure treatment at one of the in-patient centres. More parents also now appreciate the importance of obtaining dental treatment for their children. The cost of the arrangements, apart from administrative charges, during the financial year is estimated at £94,827, which includes eye, ear, nose and throat (including ambulance), and ringworm, £22,298; minor ailments, £26,187; dental cases (treatment £39,604, inspection £3098), £42,702; maintenance grants (including Cyril Henry centre), £2260; allowances for use of centres for inspection purposes, £530; remedial exercises, £150; stammering classes, £200; and initial grants to new centres, £500.

Notes, Comments, and Abstracts.

THE TREATMENT OF ALCOHOLISM.

By Paul Bousfield, M.R.C.S. Eng.,
formerly physician to the london neurological clinic.

It is nearly always the case that when an individual approaches the doctor on the subject of the treatment of his alcoholic craving he does so at a time when he is almost without any control of the habit; that is to say, he is either in the middle of a drinking bout or an exacerbation of his chronic state. His physical condition has, therefore, to be dealt with first, so that we may confidently divide our treatment under two headings, physical and psychic.

Physical Treatment.

The physical treatment assists in substituting for the alcoholic euphoria a feeling of well-being without narcotising the brain. It also helps to eliminate the gastritis, which is one of the chief factors in driving the patient towards an early resource to alcohol on the day after he has taken excess, and which, thus, leads to a continued state of excess. It is not necessary to forbid alcohol completely at once. As a rule, however, it should be reduced and left off after two days' treatment, though in some cases it will be found better to immediately discontinue it. Although the treatment can be carried out at home, the patient should preferably be placed in a nursing home for from four to seven days. If the gastritis and general malaise are very bad it is well for the patient to remain in bed for the first 24 or 48 hours. Cheerful companionship is a great accessory, and if it can be afforded a special nurse of bright disposition or some other companion should be constantly available during the short stay in the home.

If the condition is very bad, and the patient comes in with a stomach loaded with alcohol, gr. 1/10 of apomorphine hydrochloride should be given hypodermically if the heart be in fair condition. This has a twofold object: it will probably induce vomiting, but, more important, it will probably give the patient a good long sleep. For apomorphine is a hypnotic of the greatest value in alcoholism. Further doses, 1/30 gr. to 1/20 gr., may be given at intervals of six to eight hours, and one of these doses should be given immediately before the patient retires to rest for the night. On the second day a small dose of apomorphine may be given in the morning and another at bed-time. These small doses will not induce vomiting except in rare instances. If a small dose does produce vomiting it must be discontinued and some other hypnotic substituted. Hyoscyamine sulphate followed by a full dose of potassium bromide is an excellent combination under these circumstances. As soon as the patient commences treatment he should be given a mixture such as will combine a general tonic with a stomachic and will simultaneously reduce his physical craving for alcohol. The best mixture to employ is probably the following, given at intervals of two hours and a half to three hours six times daily:—

Liq. atrop. sulph.	♏ ¼.
Liq. strychnin.	♏ i.
Tr. cinchonæ co.	ʒss.
Glycerin.	ʒss.
Inf. gent. co. .. ..ad.	℥ss.

After four days this atropine mixture should be discontinued, and a mixture somewhat similar to the following substituted, and ʒi. given two-hourly in a wineglass of water:—

Ext. cascara liq.	♏ x.
Tr. cinchonæ co.	ʒss.
Aloin.	gr. 1/16.
Liq. strych. hydrochlor.	♏ iii.
Inf. gent. co. .. ..ad.	ʒi.

This may well be varied after a week to the following:—

Ext. cascara liq.	♏ iii.
Aloin.	gr. 1/16.
Tr. cinchonæ co.	ʒss.
Inf. quassia (conc. 1–7)	♏ vii.ss.
Inf. gent. co. .. ..ad.	ʒi.

Colloidal Gold.

The remaining part of the physical treatment is empirical. It consists in giving 2 c.cm. per diem of isotonic colloidal gold. As a control the author has tested this on many occasions against different inert isotonic solutions similarly coloured without letting the patients know it, and the tests have left no doubt in his mind that those treated with gold picked up more rapidly, and were more successful, than the others. The dose of gold should be divided into three parts and given after each meal. It should be started as soon as the patient enters the nursing home and continued for three weeks. It is important that both the gold and the tonics should be divided up into frequent doses, for this rather burdensome method of treatment has a very considerable moral effect in assisting the patient to remove his fears from immediate relapse. After the first four or five days the actual desire for alcohol has ceased, but the fear of the desire does not disappear until experience has shown the patient how easy it is to abstain. This fear is a most potent form of tension acting as a cause for continued alcoholism. If at this stage the patient is solemnly warned not to touch alcohol again under any circumstances a fair proportion will be freed from its slavery. Unfortunately, however, conditions of tension will recur, which if they are not understood and controlled by the patient will cause a relapse. Probably rather more than 50 per cent. of the patients cured by this method do relapse.

Psychotherapy.

A much greater percentage of permanent cures is established when we add to this physical treatment some form of psychotherapy. As to suggestion it is almost impossible to make its effects last a long period against permanent tensions, although, of course, indirect suggestion plays a part in the physical method. Where alcoholism partakes of the nature of hysteria, or compulsion hysteria, or is symbolic in some way or other of an unconscious conflict, there is sometimes a very difficult proposition to face, which only a lengthy psychological analysis is likely to solve. It is amongst these patients that most of the failures occur, for many of them are not suitable for, and cannot enter into, analytical procedure.

But the vast majority of cases suffer from what may be termed a series of normal tensions, which they do not recognise as such consciously, but which are very near the surface, and can be fairly rapidly brought to light by a much more superficial form of analysis directed essentially to a minute examination into the history of his alcoholism, including an examination into the various emotional states of his mind which were present on various occasions when alcohol was taken. An example may be of value here.

An Example.

A civil engineer, aged 35, complained that he suffered from chronic alcoholism, and that it was hereditary in his family. He had suffered from it for 12 years, and had already undergone two forms of treatment for it. One of these had been at the Norwood Sanatorium and the other at the Keely Institute. After the first treatment he had been an abstainer for six months, and then considered himself safe, but a single drink was immediately followed by three months heavy drinking daily. He then went into the other institution, and on his discharge succeeded in maintaining three months' abstinence, when he had another relapse which lasted four months, after which period he came to me for further consultation. He was placed in a nursing home for five days, and the physical treatment already described was instituted. Simultaneously, a minute investigation into the history of his alcoholism was commenced. Various kinds of impatience were almost always the starting-point for his taking alcohol. Thus, if he had to wait an hour for a message to be delivered he would find the tension of waiting intolerable. If he had a long journey to make, the idea of the boredom of wasting several hours before he could get to the end of it had a similar effect. To arrive home half an hour before dinner with no fixed programme of work to fill up that time was another source of tension which he could not bear. Loneliness was another cause of unpleasant stimuli. He liked working with three or four people around, and analysis showed that the reason of this was in order that his work might receive continual attention and praise, and under these circumstances only could he really enjoy his work. There were a large number of similar conditions which aroused more tension in this individual than they did in the average person, or, in other words, this patient was too intolerant of these conditions. Other factors which made him drink heavily, when the first exciting stimuli had passed, were the fear of the ultimate consequences of his habit and the fear that he would never be cured. He was an example of the type that drinks in order to abolish the fear of drinking.

During this investigation, which took about eight weeks, the patient was taught to consider the various points, and to give himself well-considered suggestions night and morning directed towards his habits of impatience and exhibitionism (in his work and so forth). The suggestions were not directed towards eradicating his alcoholic habit, but towards his control of the underlying tension. He was daily impressed by the physician with the needlessness of fear concerning alcohol, and the fact that if he could entirely eliminate his desire for it in a few days in a nursing home he could certainly do the same for himself on any future occasion. He was disabused of the idea that alcohol was hereditary, and he was told that at the end of the treatment he must entirely use his own judgment as to whether he attempted to take alcohol again or not. If he did so and found that he had not got complete control, he must come back at once for a little further investigation of the particular circumstances which were causing him tension which he could not face. He did, in fact, have one or two short relapses for a few days each, but after a little further investigation he succeeded in pulling himself up short and curing himself by means of a little introspection and auto-suggestion on each occasion. He has now reached the stage in which he regularly has alcoholic beverages on his dinner-table, which, however, he scarcely ever touches. And he had not had a relapse of any kind for two years.

Conclusion.

Many cases are not so simple as this, and many patients cannot afford the time for the necessary analytic procedure. In such cases, however, although frequent minor relapses may take place, the patient is nearly always in a position to cure himself by taking a week-end holiday of three days with a suitable companion. In other words, he has sufficient confidence in himself to know that if he can put behind him for a short period the tensions of home life and business he can overcome, without the aid of a physician, the gastric tension and general malaise which are the chief causes in the continuation of a bout of drinking. A frequent cause of the beginning of a bout in these minor relapses is undischarged sexual tension. If for any reason this is raised and cannot be discharged, an individual who has been prone to alcoholism tends naturally to the old habit-path which has been formed in order to avoid the tension, although he may not be fully aware that the tension is present.

COLONIAL HEALTH REPORTS.

Unfederated Malay States.

Kedah.—The report of Mr. W. Peel, British Adviser, for 1924 gives the estimated population at 350,000. The birth-rate per mille was 31·70 and the death-rate 22·41. There was considerable improvement in infantile mortality, the rate being 126·27 per mille, as against 161·73 in the previous year. The number of deaths was 7877, of which 3459 were attributed to fever, but the returns are not very reliable. The only accurate figures are those for the hospitals. Eight Government hospitals were maintained and 13,657 patients treated therein. The principal diseases were malaria, venereal disease, ankylostomiasis, dysentery, pulmonary tuberculosis, and respiratory diseases. There was a marked increase in the number of dysentery cases, but the death-rate was considerably less. In addition to the outdoor departments at the hospitals, there are seven Government outdoor dispensaries; they did good work, the number of cases treated being 18,698. Small outbreaks of small-pox occurred in different parts of the State, involving 26 cases and 3 deaths; the outbreaks were quickly controlled. 7620 injections of neosalvarsan were given for puru (yaws), as against 1183 in the previous year; the people show eagerness for this treatment. There was a decrease in the number of deaths due to diseases connected with childbirth, but the prejudice against competent medical assistance in such cases remains very strong. 20 lepers were being maintained at the end of the year at Pulan Jerejak and 5 at Pulan Pangkor Laut. The accommodation at these places is limited, and 30 patients were awaiting vacancies at the end of the year. The position with regard to lepers is not satisfactory, and it may become necessary to consider one central camp for the State. Dr. D. Bridger officiated as State surgeon throughout the year. Dr. J. T. Clarke and Dr. R. B. Hawes acted as medical officers for Kulim and Sungei Patani respectively. Dr. C. J. S. Nicholas, assistant surgeon, officiated in the post of medical officer at Alor Star. A separate health department was maintained, Dr. A. G. H. Smart being in charge until he went on leave.

Trengganu.—This is a Malay State on the east coast of the Malay Peninsula. Its configuration is long and narrow, the length being approximately 150 miles and the greatest breadth 55 miles. The western and inland half is mountainous and almost uninhabited. The population is concentrated in the eastern half of the State, along the river-plains and coastal belt. The population at the census of 1921 was 153,765, of whom 145,523 were Malays, 7246 Chinese, 211 Indians, 34 Europeans, and other nationalities 751. The highest recorded annual rainfall on the coast is 165·5 inches; the average rainfall is about 120 inches. In the coastal region the regular sea and land breezes modify the heat, which is never at any time oppressive, and the climate is both pleasant and healthy. Mr. J. L. Humphreys, the British Adviser, in his report for 1924, states that Dr. A. B. Jesser-Coope (medical officer) and Mr. Ibrahim Syed Noor (assistant medical officer) were in charge throughout the year, with a staff of eight dressers and apprentice dressers. The department was transferred in February to the completed new administrative buildings; they include store, dispensary, dressing-rooms, laboratory, and a well-equipped operating theatre. The hospital ward was completed and brought into operation in May; the second ward was completed in November; 158 cases were treated in the hospital during the year. Two major and 35 minor surgical operations were performed, and 1147 clinical pathological examinations made. Lunatic cells, a leper ward, and a vagrants' ward are under construction. The total area of the medical department reserve is approximately 18 acres of land; the site is open sandy ground, just outside town limits, and within half a mile of the sea. The commissioner of police made arrangements for the distribution through 15 police stations of drugs for simple ailments (fever, wounds, worms, sores), and a Jawi booklet of instruction on common matters of sanitation, hygiene, and infant feeding was published during the year. It is hoped that these measures will encourage the use of European medicines and help to bring the medical department more into touch with the general population. No vital statistics can be given. Of general diseases treated the more prevalent were skin diseases, intestinal worms, bacillary dysentery, diseases of respiration, yaws, and influenza. Venereal disease is not common; many cases formerly thought to be tertiary syphilis are now considered to be tertiary yaws. There was no epidemic at Kuala Trengganu during the year. There were epidemics of influenza at Kretai in July, and of bacillary dysentery at Kuala Brang in August; they were cleared up with aid sent from Kuala Trengganu. The vaccination campaign was continued during the year, 12,890 cases being successfully treated (19,750 in 1923). At the end of the year the vaccination of the whole State was completed, except for Hulu Marang and Telemong, where some opposition from religious pundits was again met with.

Perlis.—In 1924, 851 births were registered, comprising 750 Malays, 28 Siamese, 69 Chinese, 3 Tamils, and 1 Sikh. The deaths numbered 585. The number of indoor patients in the Kangar hospital was 549, and the percentage of deaths was 6·57; or, if deaths occurring within 48 hours of admission are excluded, 4·91. The daily average of in-patients was 37·46. The principal diseases treated were malaria, dysentery, phthisis, other lung complaints, ankylostomiasis, syphilis, and ulcers. The number of out-patients rose from 11,991 to 12,543. It is satisfactory to observe that Malays are taking outdoor treatment very freely. A travelling dispensary was started during the year. It distributes quinine, treats ulcers and other simple complaints, and is well patronised. Neosalvarsan injections numbered 3409, against 2027 in the previous year.

INSECTS AND PUBLIC HEALTH.

On Nov. 18th Sir Wilfred Beveridge delivered a Chadwick Public Lecture at the Royal Society of Medicine on Insects in Relation to Public Health. Sir James Crichton-Browne occupied the chair. After referring to the general educative value of the study of insect life, Sir Wilfred Beveridge said that training in entomology was very desirable for every medical man. To be of real value this training should be of such wide scope as to confer the true entomological sense, which enables the student to tackle any new problem which may arise. The chief function of insects in nature, he said, appears to be the destruction of waste and putrescent organic matter and the suppression of superabundant vegetation. At the present time we devote much attention to the destruction of the house-fly and the carrion flies because they can under some circumstances transmit certain disease germs; but if man took the proper precautions as to the disposal of infected excreta and the protection of food, the fly would not be in the unfortunate position of being a disease carrier. We should so regulate our sanitary efforts as to make the insect carrier a negligible factor in the transmission of disease, and not concentrate all our energy in destroying insect life, while failing to put our own house in order. The presence of lice was one of the many trials of the war, and great temporary loss of man power was caused by trench fever, a disease new to active service in the field, which was definitely proved to be transmitted by the louse, and the louse only. It was estimated that at least 50 per cent. of the total sick admissions among troops in the line was primarily due to the presence of vermin, and arrangements have now been made to provide mobile laundries and bathing units for an army in the field, so that in future wars the men with care should be kept entirely free from vermin. Unfortunately, however, vermin are only too common in the civil population, though by the avoidance of overcrowding and the observance of ordinary cleanliness they can be eradicated entirely.

It is quite possible that the list of insects now known to be responsible for transmitting disease will be increased, and a closer study of many household insect pests certainly appears desirable. It has been estimated in the United

States of America that the loss of labour by all insect diseases costs the country over 300,000,000 dollars each year. During the war demands for repellants against lice, mosquitoes, and sand flies were constant and pressing, and the result of trials in many theatres of war left a feeling of doubt as to their practical value; many of them were very expensive and some difficult to obtain. To sift the problem properly, and to extricate from a mass of substances expected to act as efficient insecticides and repellants those which are reliable and effective under conditions of service in various countries, it would be necessary to institute an experimental station, where the various necessary insects can be bred and maintained, so as to determine the value and action of insecticides and repellants, not only from a personal but also from an economic point of view. The bed-rock of control, said Sir Wilfred Beveridge, is efficient sanitation. The protection of food during manufacture and on exposure for sale is greatly neglected both in this country and abroad. Food is exposed to contamination by flies in shops and on the streets, in kitchens and stores, with little attempt at protection. In America, Canada, and Australia regulations are in force to prevent the contamination of food by exposure, and no food is allowed to be exposed for sale unless screened by glass or gauze. In houses the protection of food is a simple matter. The provision of screened meat safes, the screening of our store-rooms and kitchens, and the use of gauze coverings for cooked food set aside, such as those now sold as "fly foilers," is not an expensive matter and should never be neglected.

CHILD WELFARE PROPAGANDA.

A MEETING of the National Baby Week Council was held at Carnegie House on Nov. 18th, the chair being taken by Dr. W. J. Howarth in the absence of Prof. Bostock Hill. The subject for discussion was Propaganda by Local Authorities: Ways, Means, and Costs, and Dr. Howarth said that under the new Public Health Act local authorities were empowered to spend money on health propaganda, thus opening up opportunities not available hitherto. Dr. W. Allen Daley (M.O.H., Kingston-upon-Hull) spoke of various methods of health propaganda. Newspaper publicity was perhaps the most valuable, as nearly every home possessed one diligent reader of the paper who handed on news to the others and stored up information for future use. Health bulletins issued by public health departments were useful, but could only be afforded by the larger authorities. There was need for a central committee to act as a publicity and information bureau, to standardise the publications issued, so that none might show serious deviation from the general consensus of medical opinion. At a cost of from £10 to £20 a lecture, and by securing really good lecturers, Dr. Daley had found it possible to collect audiences of from 1000 to 3000, the most popular lectures being those illustrated by films. Health talks by panel doctors to their patients would be a paying proposition, and two doctors in Hull were adopting this plan. Posters were costly but useful, and broadcasting, health week exhibitions, and education of school-children were all valuable. Dr. James Fenton (M.O.H., Kensington) called attention to the fact that London was not included in the provisions of Section 67 of the Public Health Act. London boroughs did not enjoy the local patriotism enjoyed by towns, and the difficulty was rather to attract audiences than to obtain good lecturers. The ideal was to use the infant welfare centres as propaganda units and to make them educational centres. The Kensington Council had just appointed a whole-time woman lecturer, approved by the Ministry of Health, but, until the new Act applied to London, she would have to confine her efforts to maternity and child welfare. Groups of people considered by members of the audience to be in need of health education included municipal councillors, corporation officials—policemen, tramwaymen, and the like—and adolescent boys and girls.

A VISITING LIST FOR 1926.

Smith's Physicians and Surgeons' Visiting List,[1] consisting of diary, almanac, and book of engagements for 1926, appears this year for the eightieth time. A pocket-book which has not only satisfied three generations of practitioners, but has been modified by their friendly criticisms and has been constantly kept up to date in form, contents, and spacing carries its own recommendation. After the diary, which takes up the bulk of the book, come special sections for obstetric and vaccination engagements, memoranda, bills and accounts asked for, addresses of patients and of nurses, drugs and instruments wanted, and finally a list of things lent with space for name and address of the borrower. A medical man who uses the facilities here provided to their fullest extent cannot fail to profit by their methodical arrangement.

---

MALARIAL TOXIN.

Dr. I. Pentman, writing from the Pathological Institute at Omsk [1] in Western Siberia, relates the case of a boy of 10 who died comatose in a relapse of tertian (benign) malaria. Post-mortem examination showed that he had no other disease, and only *P. vivax* was found in his blood. There was degeneration and proliferation of the endothelium of the blood-vessels of the brain, also small hæmorrhages in the medulla and elsewhere, which accounted for the clinical symptoms. Dr. Pentman attributes this alteration of the endothelial cells to a definite malarial toxin, quoting in his support Pewnitsky (1903) and also Dürck in the German Medical History of the War. This toxin, even in quite acute cases, may cause waxy change in the kidneys and spleen, but not in the liver.

ROAD WISDOM.

THE familiar maxims known as "Pratt-itudes of the Road," which have recently appeared in the press, have been collected into a neat pamphlet under the title of "Road Wisdom," together with hints on garages, traffic driving, gear changing, and other subjects by expert motorists. The courtesy of the road still leaves something to be desired, and the little book contains useful reminders of road ethics. It may be had free on application to the Anglo-American Oil Co., Ltd., at 36, Queen Anne's-gate, London, S.W. 1.

A MISSION HOSPITAL IN NORTH CHINA.

THE Mosse Memorial Hospital at Ta Tung Fu, Shan Si, North China, was built as a memorial to the Rev. E. H. Mosse, who was killed by a bomb during an air raid in the neighbourhood of Covent Garden in 1918. The first annual report, dated 1924, is addressed to medical men and shows that during the year 1896 men and 568 women were treated as out-patients, a total of 2464 with return visits of 4272, making a total of 6736 attendances. There were 396 in-patients, of whom 329 were men and 67 women. Several cases necessitated abdominal surgery and there was a large amount of surgical tuberculosis, though the results of treatment in this last category were very poor. Trachoma, as might be expected, formed the bulk of the eye patients. The majority of operations were done under local or sacral anæsthesia, the latter for rectal operations. Severe rickets and osteomalacia are common and severe in the out-patient department, where syphilis is found to be widespread and the treatment of gonorrhœa is unsatisfactory as patients do not persevere. Most skin cases are syphilitic and scabies is frequent. The staff consists at present of Dr. D. S. Bryan-Brown, Dr. G. A. M. Hall, and a nursing sister with native assistants. A nursing school is in prospect.

QUICK REFERENCE.

TIRESOME as they may sometimes be, statistics are indispensable; they are the social worker's raw material, and they furnish the test of progress. The Permanent Consultative Committee on Official Statistics, set up by the Treasury in 1921, has just produced its third annual survey, covering the contents of all the official publications of 1924 and of some of those of 1925. The new volume[2] consists of two sections. The first and larger is a subject index with a comprehensive system of subheads and cross-references. The guide covers the whole field of official activities, from accidents and afforestation to women police and wrecks, but one has only to glance at titles such as children, deaths, disease, health, and so on, to see what valuable compilations of statistics are available of a kind likely to interest the medical profession. There are also of course, more specialised headings, such as factories and workshops, industrial fatigue, prostitution, vaccination and workmen's compensation—to name a few samples taken almost at random—which indicate the varied nature of the mass of information which our blue-books and other official publications contain. The second section comprises a list of those publications to which the subject index has referred. Medical practitioners and students of public health administration have seldom the leisure to read and digest the colossal output of departmental reports and returns, census figures, Royal Commissions' reports, and similar literature which H.M. Stationery Office pours forth. The less time they have, the more valuable is such a guide as this.

CHEYNE HOSPITAL FOR CHILDREN.—An exhibition and auction sale of oil and water colour paintings, drawings, engravings, jewellery, &c., in aid of the Cheyne Hospital for Children last week realised £750.

An Address
ON THE
CASE FOR THE UNBORN CHILD.

Being the David Lloyd Roberts Lecture delivered at St. Mary's Hospital, Manchester, on Nov. 17th, 1925,

By THOMAS WATTS EDEN, F.R.C.S. Edin.,
F.R.C.P. Lond.,
CONSULTING OBSTETRIC PHYSICIAN, CHARING CROSS HOSPITAL, LONDON.

It is universally accepted among us that the care of infants and young children is one of the chief concerns of the State and of society. Public interest in the matter has been one of the main forces behind those developments which in the last 25 years have brought down our infant mortality-rate from 154 to 75 per 1000. I am asking you on this occasion to consider to what extent we as medical practitioners are also concerned with the well-being of the child before birth. French obstetricians have for many years been much more concerned about all matters pertaining to infant mortality than we have, on account of their falling birth-rate, which has now reached a point at which the depopulation of that country may be said to have commenced. With their well-known gift for regarding questions in a strictly logical manner, the French have taken wide views, and many years ago Adolphe Pinard[1] pointed out that in reality the preservation of child life, or as they call it puériculture, to which there is no exact English equivalent, must be considered in relation to three periods.

(1) The *pre-conceptional period*, in which the seed to be sown and the soil in which it is to germinate are the elements concerned; (2) the *intrauterine period*, in which development is carried from the blastomere stage up to the birth of the fully developed infant; (3) the *postnatal stage*.

With the preconceptional period we are not now concerned; in this field the eugenists would like to experiment, selecting and allotting candidates for marriage mainly from the point of view of their suitability for breeding, and scarcely at all from the point of view of individual preferences, tastes, or disposition. To this field belong such interesting questions as the varying degrees of fertility of different races, the causes which underlie the dying-out of some families, and the rapid multiplication of others. Nor need we enter the domain of the pædiatrician and discuss the questions associated with infant mortality and morbidity. It is Pinard's second period which concerns us—viz., that in which the child is developing in the uterus; this period is under the care of the obstetric department of medical practice. It is therefore part of our duty to consider whether there is anything we can do, and if so what, to ensure that the intrauterine child is given the best chance of completing its development, and entering upon its separate existence under the most favourable possible conditions. Strictly speaking, this period of the child's existence includes the birth process as well, and we cannot entirely overlook, in our review of the subject, the risks to which the child is subjected in the birth-process, although it will not be necessary to enter into much detail in that particular.

The subject obviously forms a branch of what is known now as antenatal work; usually this work is looked upon as being concerned with the expectant mother, and as such it is now understood and welcomed by the public. Antenatal work should not be regarded only as a maternal safeguard, although its primary object is to ensure that the expectant mother gets through her pregnancy with the minimum of risk, and that she enters upon her labour under the most favourable obstetrical conditions. The steady, although slight, diminution which has occurred in the total maternal mortality of childbearing—i.e., the mortality from all causes—during the last 20 years, and is still continuing, is due at any rate in part to widespread establishment of antenatal clinics, and to the enthusiastic band of medical and lay assistants who work these clinics. I think I can show, however, that the fœtal and infantile mortality of pregnancy and labour is appallingly high, and unless we regard this aspect of childbearing on its merits, and as distinct from, although supplementary to, the maternal risks, we shall fail to realise its great importance.

Antenatal Care as Affecting the Child in Utero.

The question I am asking you to consider then is to what extent can antenatal care of the mother influence the well-being of the child in utero? Can we in any degree safeguard it against the risks of intrauterine death? or against premature expulsion either when non-viable, or later on when viable but heavily handicapped by prematurity? or from grave defects of development? or from transmitted intrauterine disease? or from the perils of the birth process? We have, perhaps, in the past been too much inclined to wash our hands of all responsibility for the child until it is born. We have considered its fate as lying in the hands of the two great forces which control development—viz., heredity and environment—forces which may well at first sight appear to be beyond our control. Heredity we must not stop to consider; environment, on the other hand, we should certainly consider carefully, making use of the term in its broadest possible signification.

The child in utero leads an extraordinarily sheltered existence, and can only be affected through the mother. Generally speaking, the relation of the fœtus to the mother is that of a parasite to its host, although Ballantyne, who did so much to arouse interest in the unborn child, inclined to the view that the relationship was a *symbiosis*—i.e., a kind of compromise in which parasite and host become of service to each other. The mechanism by which the embryo is formed, and the various stages of its organogenesis are completed, is an intrinsic embryonic mechanism. The embryo needs only food and shelter; given these necessaries it works out its own development. Should the supply of nutriment to the embryo be deficient in quantity or quality, or should it fall under the influence of poisonous substances which reach it from the mother's blood, or should its resting place be subject to injury from without, the environment will be so modified as to deflect the normal course of development and perhaps to render the continued existence of the embryo impossible. The number of infectious diseases which can be transmitted to the fœtus through the placenta is a very large one, and no useful purpose would be served by my detailing them to you. In some other conditions, such as the pregnancy toxæmias and chronic renal disease, the placenta may be damaged to such an extent as to cause the death of the fœtus. We know little or nothing of the effect which minor departures of maternal health produce upon the placental exchanges.

It is, perhaps, not unreasonable to suppose that not only what the pregnant woman eats and drinks, and the air she breathes, but also her occupations and even her emotions, may exert an influence upon the child in her womb. We know that the state of the circulation may be profoundly influenced through the nervous system, and the character of the glandular secretions may be modified by psychical influences. I have not time to mention instances of these changes, but given their occurrence in a pregnant woman it is not unreasonable to suppose that the placental interchanges may be modified by them. It may be a long time before we are able to estimate the degree of importance which should be attached to considerations such as these which are in the meantime merely speculative, but we shall, as we proceed, find reason to admit that the placental interchanges probably cover much that cannot properly be included in the functions of nutrition and respiration.

Next to the welfare of the mother our great concern in antenatal work is that the child should complete its proper period of intrauterine development and be born not only alive, but with the best possible chance of survival. Let us first of all consider what are the present chances of the child completing its intrauterine development and being born alive. It may be cut off either by miscarriage or by stillbirth; and further, if born alive, it may be born in a condition which renders its survival impossible, or at the best a matter of great uncertainty.

As regards the frequency of miscarriages there are, of course, no official figures in this or any other country. Some years ago my colleague, Dr. Amand Routh,[1a] attempted to estimate the frequency of miscarriages, partly from the experience of several clinical observers, and partly from returns obtained from certain cities in the U.S.A. His figures indicated that almost one in five of all pregnancies terminated in miscarriage. If this figure is to be accepted for our own country it would follow that in England and Wales in the year 1924 something like 190,000 pregnancies terminated in miscarriage. I do not suggest that we should accept this figure without reservation, but there can be no doubt that miscarriage is a very frequent occurrence.

Regarding stillbirth there is information available in this country but it is limited. We know the number of stillbirths notified under the Notification of Births Act, but no information as to the cause of death is given for stillbirths at all. Another source is the returns which are published by some but not by all of our lying-in hospitals. According to the report for 1924 of the chief medical officer to the Ministry of Health, over 25,000 stillbirths were notified in that year. This corresponds to a rate of 3·3 per cent. of live births. The total maternal mortality of child-bearing for the same year was 3·7 per 1000 live births, so that the stillbirth-rate alone, and taking no account of miscarriages, was roughly ten times greater than the total maternal mortality.

In France in the year 1922, according to Couvelaire,[2] the proportion of registered stillbirths (and only those are included which had passed the sixth month) amounted to 44 per 1000 live births. The same author shows that in France it is in the great centres of population that the highest stillbirth-rate is found; Paris had a rate in that year of 93 per 1000; a group of large towns a rate of 69 per 1000; rural departments only 26 per 1000. Fœtal death is, however, not the only consideration to be borne in mind. Many infants born alive die in the very early days of the neonatal period from injury received in labour, from prematurity, from disease, or from debility of unknown origin. It is clear, therefore, that if we are properly to envisage the problem of prevention we must endeavour to bring into view all the conditions which are capable of influencing the well-being of the child during its intrauterine development.

Ballantyne [3] divided the duration of intrauterine life into three periods, and it will be a help to us to make use of his classification. The three periods were: first, the *embryonic period*, which extends from the act of fertilisation to the end of the eighth week; second, the *fœtal period*, from the end of the eighth week to the onset of labour; third, the *intranatal period*, comprising the birth process itself.

1. THE EMBRYONIC PERIOD.

The embryonic period is that in which are laid down the sex of the offspring, its inheritance of hereditary characters, and the general plan of all the organs of the body. Ballantyne also speaks of it as the organo-genetic period. Sex and inheritance are decided, according to modern views of development, at the moment of the first segmentation of the fertilised ovum. Malformations of all kinds are initiated in the embryonic period. The mechanism by which the sex of the individual is determined and also its inheritance of hereditary characters, in view of recent biological advances is now clearer than it has ever been before; it even appears to be not impossible that experimental means may be found of altering the sex ratio, that is, the proportion of males to females, in the case of some creatures such as insects. It is therefore not out of the question that not we ourselves, but those who may follow us, will discover some practical method of influencing the segmentation of the ovum in the direction of maleness, or femaleness, at will. It will consequently be well for us to keep in mind as clear a conception as we can of the biological hypotheses of to-day relating to the determination of sex and of heredity.

Sex Determination.

Modern biological research first placed the difficult subject upon a firm foundation in the case of insects and certain genera of birds, and there is little doubt that in principle these results are applicable to the higher animals.

Sex is determined at the moment of fertilisation—i.e., when the male and female gametes unite, and the arrangements are such as to produce an approximately equal number of individuals of either sex. When the gamete or sex cell divides its nucleus breaks up into a series of dense, deeply-staining bodies known as chromosomes; each species of creature has its own special number and arrangement of chromosomes which are constant for that species. After division of the gamete each daughter cell contains the same number and arrangement of chromosomes as the parent cell. Before the male and female cells fuse in the act of fertilisation, certain preparatory changes take place in the chromosomes. They become arranged in pairs, and as a result of cell-division the two members of each pair separate from one another so that each resulting nucleus contains only half the original number of chromosomes. This is called the *reduction-division* and it is accomplished in the human egg-cell by the extrusion of the polar bodies. In the chromosomes are carried the elements which determine sex and also those which determine hereditary characteristics. The reduction division is the mechanism by which variations in inherited characteristics are produced, the elements extruded at this moment representing the hereditary traits which will be absent in the new individual.

It is obvious that this mechanism gives possibilities of an almost endless variety of combinations of hereditary characteristics, and is comparable to the shuffling of a pack of cards. It offers an easy explanation of the differences both physical and temperamental which are so commonly observed in children of the same parents. Indeed, with the exception of "identical twins"—i.e., uniovular twins of the same sex and identical physical characteristics, these variations are almost universal. The close similarity of uniovular twins of the same sex strongly supports the view that this form of twin results from the fertilisation of a single egg-cell.

It is known that in certain insects the number of chromosomes differs in the two sexes, the female having one more than the male; a similar difference between the two sexes exists in the case of many other creatures. The sex-chromosomes are called X-chromosomes and in the simplest form the female has two similar chromosomes XX; in the male there are two dissimilar sex-chromosomes—viz., XY, the female always has XX. After the reduction-division has occurred the female gamete will, in consequence, always contain an X chromosome; in the case of the male gamete one-half will contain an X, another will contain a Y chromosome. If an X female fuses with an X male the result will be XX—i.e., female; or if X female fuses with Y male the result will be XY—i.e., male.

Certain experimental work which has been done in the case of insects and birds, however, appears to indicate that the proportion of individuals of either sex may be altered to some extent by external influences. Leiter found in experimenting with the eggs of certain moths that by exposing them to a temperature of 35–37° C. (about 90° F.) the proportion of male individuals was markedly increased, while conversely a similar exposure to a low temperature markedly decreased this proportion. In the case of pigeons experimental work has so far advanced that in the words of Julian Huxley,[4] "there exists a very strong probability that we shall be able to find some agency which will alter the sex-ratio to suit our wishes."

He would be a bold man who would affirm that these results are incapable of extension to the case of the higher animals such as the mammalia. At the present moment we are not justified in assuming that they can be so applied, for it is obvious that in animals which carry their young in the womb, the fœtal environment could be modified, if at all, only with the greatest difficulty in the direction of altering its temperature. Of course, rises of body temperature are not uncommon, but when fever occurs in pregnant women the ovum is subjected not merely to the raised temperature of the body but also to the toxic bodies which result from fever or those to which the fever is due. The experiment of subjecting the mammalian ovum during segmentation to an elevated temperature uncomplicated by other changes seems almost impossible of attainment.

The idea that it was possible by extraneous measures to determine the sex of the unborn child has been tenaciously held since the beginning of history. Gifts to pagan deities and pilgrimages to shrines of saints represent the appeal to the supernatural which human nature is prone to make on all critical occasions. These are, however, not, strictly speaking, therapeutic measures and do not concern us now. The belief still persists among the laity that matters can be so arranged by husband and wife as to produce a child of the desired sex, but this belief has no basis in accredited facts.

Malformations.

Let us in the next place consider the causation of malformations. We have seen that the embryonic period is the time at which those deflections from the normal course of development occur which result in the production of malformations of all kinds. There was no clear idea possible of the causation of these defects until it was shown by experiment that they could be produced by subjecting the developing embryo to various kinds of abnormal stimuli; from small beginnings an extensive field of experimental teratology has now been covered, and it appears that there is no known malformation which cannot be experimentally reproduced, in the case of certain classes of animals. It is, of course, admitted that the particular stimuli which have been made use of experimentally could not well be applied to the mammalian embryo. They are all sufficiently powerful to produce actual injury, and their effects may fairly be classed as traumatic. These experiments lead us to believe that the cause of malformations in man must be sought in some alteration of environment which would be comparable to the physical or mechanical stimuli used in these experiments.

It would serve no practical purpose to enter at all fully into it, but one or two examples may be cited of the results of injury of the segmenting ovum. The expression "injury" must be understood to include all abnormal stimuli, mechanical, thermal, chemical, and electrical.

Some of the earliest experiments were made with the incubation of hen's eggs, when it was found that variation in the temperature of the hatching medium in either direction resulted in the production of a large percentage of deformed chicks. By shaking the eggs, or standing them up on end St. Hilaire produced double-monster chicks. Other observers worked with chemical stimuli, and it was found that the injection of alcohol into the blastomere of the incubating egg produced a large percentage of deformed chicks. The more toxic forms of alcohol, such as isopropyl alcohol, might result in the appearance of over 80 per cent. of such deformities (Féré).[5]

More recently experiments have been made with the ova of sea-urchins and similar forms. It has been discovered that by violently shaking the fertilised ova in a centrifuge, the component cells become separated from one another, and each separate cell may then develop a complete individual of proportionately smaller size than the normal. These latter experiments support the view that triplet, quadruplet, or quintuplet pregnancy may possibly be accounted for, not by simultaneous fertilisation of more than one ovum, but by traumatic separation of the cells of the blastomere at a very early stage of its formation. With ascidian ova it has been shown that if, in the two-cell stage, one cell is destroyed by heat the other develops into a half-embryo. Similarly, if in the four-cell stage the two posterior cells are destroyed the remaining ones develop into an embryo minus a tail and other hinder parts. Another observer found that in the frog also a hemi-embryo could be produced in much the same manner as in the ascidian, but his results lack confirmation (Rowe). Further, if the frog's egg be turned upside down in the two-celled stage, double-bodied or double-headed embryos may result. Siamese twins and two-headed forms in man probably result from partial separation of the cleavage cells. In vertebrate animals spina bifida has been produced by changes in temperature, and in other cases cyclops has been produced.

We must not conclude that traumatism is the invariable cause of malformations, because F. W. Browne[6] has shown that there is good reason to believe that the anencephalic fœtus is the result of non-development of the pituitary body. And further, remarkable effects may be produced by alterations of nutrition. At any rate, it is clear from what has been said that deformities should not be regarded as mere freaks of the developmental forces, or as the result of hereditary vicious tendencies. The future may possibly teach us the nature of the terato-genetic traumata which operate in man and how to avoid them. At the moment we have no gleam of light on the subject.

Causes of Embryonic Death.

Of the actual causes of death in the embryonic period we know little, and there is no reliable basis on which an estimate can be formed of the frequency of embryonic death. It is probable that a considerable number of miscarriages occur which are not the result of disease, but are either produced by slight traumatic causes or are due to a certain unfitness of the early embryo to complete its development. In all creatures the reproductive process is attended by a certain amount of wastage.

It is not the rule of nature that all the ova which ripen and are discharged from the ovary should become fertilised, nor that all those which do become fertilised should complete their development into new individuals. The character and cause of this normal wastage have been carefully examined by Arthur Robinson[6a] in the case of horses and ferrets, the former being either Clydesdales or thoroughbreds, about which accurate details as to mating and foaling could be obtained. Robinson showed that in ferrets a considerable proportion of the zygotes or fertilised ova perished at various stages of development, although in the same uterine cornu neighbouring zygotes on either side of them developed normally. He regarded their death as being due to structural unfitness of the zygote to fulfil its destiny, and not to any abnormal maternal condition. In this conclusion he was no doubt right. The occurrence of fœtal death in the case of mares is not clearly proved by Robinson's data, and it would appear that his conclusions are mainly to be read as applicable to animals which produce their young in litters, and in whom, consequently, a high fœtal death-rate would not be prejudicial to the continuance of the species.

In animals which produce only one, or at the most two, young at birth, like mares, a high fœtal death-rate would be of graver significance. It may be admitted, however, that in man it is, at any rate, probable that a certain unknown proportion of the abortions which occur, and for which no pathological explanation can be found, may be set down to the reproductive wastage described by Robinson.

2. THE FŒTAL PERIOD.

Before proceeding to consider the conditions which are mainly accountable for loss of fœtal life, it will be well to review one or two matters which are concerned with what may be called the general hygiene of the fœtus in utero. Let us look at the case of the child of healthy parents, suffering from no disease which can be transmitted to it such as the infections, or which can prove inimical to its continued existence such as toxic albuminuria and eclampsia. Besides providing it with food and shelter, does a healthy mother influence the condition of the child in utero by her own physical health, or by her occupation, or by the struggle for existence?

Transmission of Immunity.

On the threshold of this question lies the subject of the transmission of immunity. Is the new-born child in any way prepared, by the transplacental passage of immunity bodies from the mother, to resist infection acquired after birth? Clinicians have frequently drawn attention to the great susceptibility of young infants to infections of all kinds, and the view has been often expressed that the child does not acquire a power of actively resisting infection until the second year has been passed. Passive immunity may, however, to some extent be acquired from the mother—i.e., antibodies present in the mother serve to confer a certain measure of protection upon the child while its own powers of resistance are undeveloped. It will, perhaps, be of interest to summarise as well as I am able the present state of our knowledge on this subject.

For a long time it was thought that such antibodies as the young infant possesses reach it through the mammary secretion, and that mainly through the special secretion of the first two to three days, known as the colostrum. This view was the outcome of experimental work done on ruminant animals such as the cow, the goat, sheep, and also on pigs and horses. In these animals antibodies do not reach the fœtus in utero at all, but they are present in large amount in the breast milk, and can be found in the blood of the young after suckling. Two American observers, Kuttner and Ratner,[7] have recently shown that these results do not hold good for all mammalia, and that in certain rodents antibodies can be detected in the umbilical blood at birth. Similarly, these observers have shown that antibodies can also be found at birth in the blood of the new-born human infant. This difference between ruminants and rodents is attributed by these investigators to a difference in placentation; in the former the placenta consists of a double layer of epithelium, while in rodents and in man the placental epithelium consists of only a single layer, and is therefore more readily permeable.

The experimental work has been done mostly with the antitoxin of diphtheria, because in the cutaneous reaction known as the Schick test we have a very convenient means of checking the individual power of resistance to the diphtheria toxin. I may remind you that the Schick test consists in the intradermal injection of a specific dose of a graduated solution of diphtheria toxin; if this dose is inadequately "resisted" by the tissues a local reaction occurs in 24–36 hours; if the resistance is adequate there is no local reaction. A positive result is therefore an indication that the individual is inadequately protected.

Kuttner and Ratner found in a series of 30 observations that whenever the mother gave a Schick negative test, the diphtheria antitoxin could be detected in the blood of the umbilical cord as well as in that of the mother. In a further series of 15 cases in which quantitative tests were applied, they found that the amount of antitoxin in the umbilical blood was identical with that in the mother's blood. This observation has been amply confirmed by other investigators. There is, therefore, in these animals (rodents) no loss of antitoxin in passage through the placenta, which clearly allows these bodies to pass through freely. These immunity bodies transmitted from the mother's blood during pregnancy would confer immunity on the child, in the same degree as it exists in the mother.

The observation was first made in 1895, and has since been established beyond question by numerous observers, that the new-born child is protected against diphtheria. According to Zinsser,[8] 93 per cent. of new-born infants give a negative Schick reaction provided that the mothers are negative also. This protection diminishes during the first year, so that at the beginning of the second year two out of every three infants have no antitoxin in their serum. The immunity of the new-born infant is brought about by the transplacental distribution of the antitoxin present in the mother's blood, and, as we have just seen, the amount of antitoxin is the same in both the mother's and the child's blood.

These American authors further made a comparison between the protective value of the umbilical blood and that of the colostrum in guinea-pigs. In 9 cases out of 12 the cord-blood gave complete protection against a lethal dose of diphtheria toxin, while colostrum gave complete protection in only 1 out of 12; further, they found that the antigen content of the blood of the young was not raised after suckling had begun. It is, therefore, clear that in these creatures immunity bodies pass to the fœtus mainly through the placenta, and only to an inconsiderable extent is this amount supplemented from the mammary secretions. In the case of calves, on the other hand, it appears that the colostrum is the chief vehicle by which immunity bodies pass to the young; this fact is confirmed by a striking clinical observation that while calves deprived of suckling regularly fall a prey to the disease known as "scours," a form of *Bacillus coli* infection characterised by diarrhœa, those which are suckled are completely protected from the disease. Owing to the fact that the rodents and man have a similar form of placentation—i.e., a single-layered epithelial filter, it is probable that results obtained with these animals are more likely to throw light upon what occurs in man than are experiments with ruminant animals.

One further observation I should like to mention in relation to immunity. Kleinoff[9] claims to have shown that the umbilical blood of the new-born child possesses definite hæmolytic or bacteriolytic powers. He found that if the serum of the infant's blood were added to cultures of certain bacteria the growth of these organisms was inhibited, and in some cases the bacteria were broken up. The effect is the same, although less in degree than that obtained with the blood-serum of an adult. It is clear, therefore, that the fœtus acquires certain passive immunities in utero through the placental interchanges. What may be the actual extent of this process of passive immunisation of the child we cannot tell in the meantime. A very wide field is opened up by these suggestive experiments, and although at present the number of infections in respect of which it is possible to confer passive immunity is not large, it must be remembered that the science of immunology is in its infancy, and great developments may be witnessed in the future.

Effect of General Maternal Conditions.

Next we must consider to what extent the well-being of the fœtus in utero can be influenced by general maternal conditions such as nutrition, occupation, hardship, and what we may perhaps term "nervous stress." The tendency within the profession has been to consider that the child in utero, like all parasitic organisms, would succeed in looking after itself no matter how much the mother might suffer from such conditions as hardship or under-feeding. It is doubtful if this view can be maintained absolutely, and there are certain facts and considerations bearing upon the point to which I should like to draw your attention. It will be convenient if in the first place we consider conditions which may conceivably be detrimental to the fœtus in utero without actually terminating in miscarriage or stillbirth.

If an inquiry is made as to what extent the occupation and environment of the expectant mother may affect the well-being of the child at birth, a serious difficulty is at once encountered—viz., that it is very difficult to find any reliable criteria of well-being in the new-born except that of weight and length. It does not necessarily follow that the heaviest infants are the most vigorous at birth, or that they make better progress than the others. There are, undoubtedly, exceptions, but, as a rule, babies under the average weight at birth are less vigorous than those of normal or more than normal weight. It does not necessarily follow that every few grammes added to the weight of the child add in corresponding degree to its vigour and to its chances of survival. It is, however, an arguable proposition that such is the case, and certain investigations have been made upon this assumption which are worthy of our consideration.

Effect of Maternal Occupation on the Child.

Adolphe Pinard [1] was for many years an advocate of the view that women engaged in industry who continued at their work during the last three months of pregnancy showed a marked tendency to premature confinement; their infants were accordingly under-sized and less vigorous than full-time children. He carried out an inquiry as to the weight of the child at birth in different classes of women, with a view to testing the effects on the child of the mother's occupation, and particularly as to the value of cessation of work and admission to the clinique well in advance of the confinement. Investigations on similar lines were made about the same time by Letourner.

The results of Pinard's examination of 4445 cases were as follows:—

	Average weight at birth.
1. Women industrially occupied up to time of confinement and working in standing position	2787 g.
2. Women industrially occupied working in sitting position	3138 g.
3. Women who ceased their work from one to three months before confinement	3362 g.

This difference between the women who were engaged in hard industrial work up to confinement, and those who had ceased work for at least a month, is represented by an average increase in the weight of the infants of the latter of 575 g. The increase in the children of the women who rested is attributed by Pinard solely to the fact that these women carried their infants to term, while an undue proportion of the others did not.

Letourner's results were very similar. He divided the subjects of his inquiry into three classes as follows:—

	Average weight.
1. Women who worked up to confinement	3010 g.
2. Women who ceased work for at least ten days ..	3290 g.
3. Women who were admitted to the clinique before labour	3366 g.

An independent inquiry was being carried on about the same time in Germany and the results were reported by Fuchs in 1899.[10] His work was done on somewhat different lines and is perhaps more convincing than that of Pinard. He rightly thought that in investigating the effects of maternal occupation on the weight of the child the comparison should be made strictly between infants of an equal degree of development, and he accordingly excluded all premature infants from his inquiry. Incidentally, it may be said that he disagreed with Pinard's conclusion that continuance in industrial work tended to result in premature labour.

Fuchs classified his cases into occupational groups:—

	Average weight at term.
1. Domestic service and allied occupations—	
(*a*) No hospital treatment	3285·33 g.
(*b*) Hospital treatment	3437·16 g. (+ 152)
2. Dairy and other agricultural work—	
(*a*) No hospital treatment	3324·95 g.
(*b*) Hospital treatment	3354·50 g. (+ 30)
3. Factory workers—	
(*a*) No hospital treatment	2948·35 g.
(*b*) Hospital treatment	3123·75 g. (+ 175)
4. Light work only—	
(*a*) No hospital treatment	3196·42 g.
(*b*) Hospital treatment	3305·76 g. (+ 109)
5. Married women, housekeepers, &c.—	
(*a*) No hospital treatment	3378·45 g.
(*b*) Hospital treatment	3416·15 g. (+ 136)

The main conclusions which appear from Fuchs's observations are (1) that the infants of factory workers are smaller than those of the other classes, (2) that the infants of all classes of patients benefit by a hospital régime during the latter weeks of pregnancy, (3) that especially women who work in factories, and to a less extent town workers generally, benefit more from the hospital régime than do women engaged in outdoor agricultural occupations. These conclusions serve to emphasise the generally accredited view that country women engaged in farm work, who are necessarily of good physique, who are engaged in outdoor occupation, and are well-fed, are the most likely to produce vigorous and well-developed infants. The problem of the weakly infants whose chances of survival are below the average is essentially an urban problem.

Effect of Maternal Privation and Hardship.

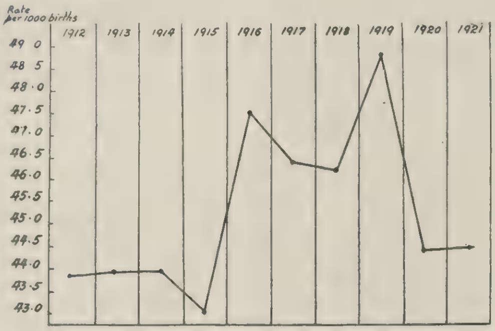
Closely linked to the question of fatiguing occupation is the question to what extent privation and hardship endured by the mother during pregnancy can influence the well-being of the child in utero. The experience of the Central European countries during and immediately after the war has shown us the result of an experiment on a scale far exceeding that which would be possible under any ordinary circumstances. The reports from Germany and Austria were almost unanimous that no appreciable diminution could be detected in the average weight or length of infants born during these years of privation. One authority, Prof. Klotz,[11] of Lübeck, has, however, noted a point which is worthy of consideration. In the years 1919 and 1920, which were perhaps even more difficult for the lower classes in Germany than the actual war period, Klotz found that if a comparison were made between the legitimate and illegitimate infants it was found that while the former showed no difference in weight between pre-war years and these two post-war years, it was not so with the illegitimate infants, and he gives the following figures:—

Average Birth Weights Before and After the War (Klotz.)

	Legitimate.		Illegitimate.
1913	3742 g.	....	3671 g.
1914	3819 g.	....	3821 g.
1919	3789 g.	....	3424 g.
1920	3810 g.	....	3559 g.

It is to be borne in mind that for a long time before the war the proportion of illegitimate births in Germany was unusually high—viz., between 9 and 10 per cent. of the total births. This already high proportion increased during the war period because the number of legitimate births became reduced at a much greater rate than the illegitimate ones. The stress of hardship and want will naturally fall more heavily on the illegitimate mothers than on others, and it is not unreasonable to suppose from these data that there is a limit beyond which such conditions as privation and hardship would become definitely detrimental to the child in utero (see chart).

While we are speaking of the effects of war conditions, I should like to call attention to a further point—viz., their influence upon the occurrence of stillbirths. The accompanying chart shows the changes which occurred in the stillbirth-rate in France during the period covered by the war and the two following years. The figures are worked out in their ratio to the total births, and it will be seen that a marked rise in the stillbirth-rate occurred during the years 1916–19.



The figure for 1914 is a provisional one.

The corresponding figures for our own country are not available. War conditions included so many different varieties of privation and nervous stress that it is impossible to attempt any explanation of their modus operandi. We must simply record the fact that there is a point beyond which such conditions are unfavourable to the proper development of the fœtus in utero.

There is one more study of the effects of maternal nutrition on the new-born child to which I should like to refer—viz., that published by Darwall Smith[12] in 1916. He closely examined the records of over 6000 hospital cases in London and Dublin with regard to the ratio of height to weight, the nutritional history, and the observed nutritional condition of the mother on admission and on discharge from the hospital. He divided his cases into three groups—those in which the nutritional condition of the mother were (*a*) bad, (*b*) average, and (*c*) good—and his conclusions as regards the influence of these conditions (1) on fœtal mortality, (2) on prematurity, (3) on the birth weight are of great interest.

	Condition.		
	Good.	Average.	Bad.
Fœtal mortality	1·9 %	1·1 %	7·7 %
Prematurity	1·3 %	2·7 %	11·9 %

As regards the birth weight, Darwall Smith found that there was little difference between the classes of bad and average nutrition, but the infants in the class of good—i.e., over-average—conditions were decidedly above the average weight.

These observations suggest that a bad nutritional condition of the mother greatly increases the percentage of stillbirths and of premature labours, and slightly decreases the birth weight. The mothers who were over-nourished showed a considerable average increase in birth weight, and a higher percentage of them were able to suckle their babies.

Effect of Maternal Diet.

A question related to that which we have just considered, but in reality distinct from it, is whether specific deficiencies in the mother's diet can influence the development of the fœtus. It is obvious that this may be so, although general insufficiency of food may be without effect. In its clinical aspect this question has hardly been explored at all, so far as I am able to find, but there is a certain amount of experimental work which I think deserves notice. In 1921 Reynolds, of Boston, well known in the United States for his interest in the subject of sterility, published in conjunction with Macomber a series of observations on the manner in which the fertility of rats could be influenced by feeding them on specifically deficient diets.[13] In his experiments he took a certain strain of albino rats which had been inbred for 34 generations, and whose fertility-rate was well determined. The rate was somewhat lower than that of rats of a heterogenetic strain.

For the purpose of his experiments the rats were fed upon four different kinds of deficiency diet; the deficient elements were not absent from the diet, but were present in quantity somewhat less than the standard quantities of the stock diet, with which they were compared. The four varieties were:—

1. Low in fat-soluble vitamin.
2. Low in protein.
3. Low in calcium.
4. Double deficiency — i.e., low in protein and fat-soluble vitamins, high in carbohydrates.

The test consisted of determining the number of matings which proved fertile, and resulted in litters, under each form of diet, and the results were as follows:—

	Per cent.		Per cent.
On stock diet	65	On diet No. 2	31
On diet No. 1	55	On diet No. 3	14

In addition to diminishing the number of fertile matings it was found that the progeny of these animals did not begin to breed until a more advanced age than the stock rats, and the total period of their sexual activity was reduced. By continuing the deficiency diet through several generations complete infertility could be produced. These infertile rats were apparently well-developed animals with the exception of those bred under a double-deficiency diet which were feeble and undersized.

The authors made a further very interesting observation—viz., that abortion with a macerated fœtus occurred in eight instances out of a comparatively small number of rats on a double-deficiency diet. After an extensive search through the literature of rat-breeding they had failed to discover an instance of this occurrence under other conditions. The authors further state that Steinbock has also reported the birth of macerated fœtuses in cattle and swine fed on similar deficiency diets.

It cannot be questioned that these observations of Reynolds and Macomber are very suggestive. It is difficult to make tests of sufficient numbers of cases in clinical work, but occasional opportunities may arise of seeking the explanation of failure to conceive, or after conception, of failure to carry the child to term, in deficiency of some important dietetic element. We have all seen those rare but puzzling cases in which a woman has on several occasions carried her child almost to term, and then for some quite obscure reason the fœtus has died in utero before labour has set in. Such cases, of course, are generally syphilitic, but failing this explanation, it would be worth while to explore the possibility of a dietetic deficiency being the operative cause. Occasional instances of what used to be called "habitual abortion" may also possibly arise from some dietetic fault.

The calcium content of the diet of an expectant mother is especially deserving of consideration. Blair Bell has estimated that the mother parts with 800 g. of calcium during the nine months of pregnancy; unless the element is freely renewed in the diet, it is quite possible that the fœtus may be calcium-starved with disastrous effects to its vitality. Milk and green vegetables are the principal dietetic sources of calcium, and this element can, of course, be readily supplemented medicinally.

Clinical Lecture
ON
TRIPLE PUNCTURE:
LUMBAR, CISTERNAL, AND VENTRICULAR.

Delivered at Westminster Hospital

BY SIR JAMES PURVES-STEWART, K.C.M.G., C.B., M.D. EDIN., F.R.C.P. LOND.,
PHYSICIAN TO THE HOSPITAL.

WITHDRAWAL of the cerebro-spinal fluid is a familiar clinical procedure which has now been practised regularly for over 20 years. It is recognised as being of the highest value, sometimes for purposes of diagnosis, in other cases for treatment. A large and increasing literature has grown up with regard to this fluid, its pressure, its cellular content, its chemical composition, and its various pathological reactions, such as the Wassermann reaction, the colloidal gold and colloidal benzoin tests, and so on. These reactions I do not propose to discuss, but shall confine myself to a consideration of the various ways in which the cerebro-spinal fluid can be withdrawn for purposes of examination.

ANATOMY.

Let us first recall a few anatomical points. It is now well recognised that the cerebro-spinal fluid circulates slowly through an endothelial-lined system of its own. It is secreted by the capillaries of the choroid plexuses into the cerebral ventricles, much in the same way as the watery constituent of the urine is secreted by the renal capillaries into the glomeruli of the kidney. Starting at the lateral ventricles, the cerebro-spinal fluid flows slowly downwards along the Y-shaped foramen of Monro into the third ventricle. Here it receives accretions of fluid from the small plexuses within this ventricle; it also receives, through the infundibulum, the secretion of the posterior lobe of the pituitary gland. Then, passing along the aqueduct of Sylvius, or iter, the fluid reaches the fourth ventricle, again receiving accretions from the choroid plexuses of the fourth ventricle. From the fourth ventricle it passes back into the *cisterna magna* or *spino-cerebellaris* through three openings in the pia-arachnoid. One of these openings, the foramen of Magendie, is situated mesially in the roof of the fourth ventricle; the others are the bilateral foramina of Luschka, situated in each lateral recess of the ventricle. The direction of the stream now changes. It turns forwards, coursing from the cisterna magna along the ventral aspect of the medulla, pons, and mid-brain, to the wide and deep *cisterna basilaris, pontis*, or *interpeduncularis*, a quadrilateral space extending laterally from one temporal lobe to the other and postero-anteriorly from the upper border of the pons to the optic chiasma. At the chiasma the stream turns upwards again to enter another cistern, the *cisterna terminalis*, a triangular space whose base is at the optic chiasma whilst its apex is directed upwards beneath the anterior end of the corpus callosum, surrounding the anterior cerebral arteries. The basilar cistern comprises three parallel longitudinal channels, one in the middle line, surrounding the basilar artery, and one on each side, enclosing the internal carotid artery. From each side again a lateral continuation passes outwards and upwards, constituting the *cisterna fossæ Sylvii*, leading along the course of the middle cerebral artery. Finally, there is a *cisterna venæ magnæ*, situated between the hinder end of the corpus callosum and the upper surface of the middle lobe of the cerebellum, containing the posterior cerebral arteries and the vein of Galen.

Passing from the cisterns along these various peri-arterial arachnoidal channels into the cerebral fissures, the cerebro-spinal fluid is ultimately distributed to the meshes of the subarachnoid space in the sulci of the cerebral cortex and to the arachnoidal villi and Pacchionan bodies. In these situations it is reabsorbed into the blood circulation through the venous sinuses in the dura mater. There are also certain funnel-shaped prolongations of the subarachnoid space which surround the cranial and spinal nerves as far as their foramina of exit through the dura mater. These are specially evident around the optic and trigeminal nerves. Thus the Gasserian ganglion of the trigeminal nerve lies in a special little arachnoidal pond, a diverticulum of the cisterna pontis, known as the *cavum Meckelii*. The subarachnoid cerebro-spinal fluid also communicates through the internal auditory meatus with the perilymph of the internal ear. From the cisterna magna there is also a slow downward current around the spinal cord, leading to the lowest end of the spinal subarachnoid space. Some of the spinal fluid escapes en route into the interpial lymph spaces and thence outwards along the peri-radicular lymph spaces. There is also a contrary upward current within the spinal cord itself, leading upwards to the fourth ventricle.

PHYSIOLOGY.

Let me also recall one or two physiological points. By experiments it has been shown that most of the cerebro-spinal fluid is reabsorbed through the cerebral arachnoid spaces, and only a small proportion through the spinal subarachnoid space. It is doubtful whether any absorption takes place from the cisternæ, whose main function is that of large conduits leading the fluid from the ventricles towards the surface of the brain.

The posterior lobe of the pituitary gland pours its secretion into the cerebro-spinal fluid of the third ventricle through the hollow infundibulum. The cerebro-spinal fluid also receives various products of metabolism from the nerve centres through the perineuronal and perivascular lymph spaces of the brain and spinal cord, which communicate directly with the general subarachnoid space.

Some poisons, such as salvarsan, which easily gain entrance into the blood stream, are held up and prevented from reaching the central nervous system by the activity of the choroid plexuses, which act as a protective hæmato-encephalic barrier. On the other hand, various other drugs are not held up, but pass through the choroidal filter and can be detected in the cerebro-spinal fluid. Thus, for example, urotropin taken by the mouth can be shown to yield formic aldehyde in the cerebro-spinal fluid, whilst in acute alcoholic poisoning, as we have repeatedly observed for ourselves in hospital, alcohol can be demonstrated in the fluid within two or three hours after it has been drunk.

POSSIBLE SITES FOR WITHDRAWAL OF CEREBRO-SPINAL FLUID.

From what we have already seen, it is evident that there are various ponds or collections of cerebro-spinal fluid, more or less accessible to the clinician, from which we can obtain samples of the fluid for purposes of examination. Let me mention one or two of the less common sites first.

Fractures of the base of the skull may permit of escape of cerebro-spinal fluid from the cranium. Sometimes this occurs through a broken cribriform

(*Address to be concluded next week.*)

plate of the ethmoid, so that the fluid leaks down into the nose; sometimes it results from fracture of the temporal bone, causing escape of fluid through the ear.

Some years ago Beriel, of Lyon, devised a method of passing a needle along the orbit into the *cisterna basilaris*. The needle was passed along the orbit, close to its outer wall, and pushed through the dense fibrous tissue which fills up the sphenoidal fissure. Clinicians, however, found this method inconvenient, not only on account of its painfulness, but also because of the liability to wound the cavernous sinus.

Another rare and accidental path of obtaining the fluid is from the cavum Meckelii, through the foramen ovale at the base of the skull. This happened to me one day when I was injecting the Gasserian ganglion with alcohol in a patient with trigeminal neuralgia. The needle had been introduced longitudinally along the foramen ovale in the usual way, from before backwards. Before injecting the alcohol, I happened to notice that clear fluid was dropping from the facial end of the needle. This was collected in a test-tube and was found to give the ordinary reactions of cerebro-spinal fluid, including its reaction for glucose. It was thus evident that the point of the needle was in the cavum Meckelii. This route, however, is too uncertain to be reached except by a happy accident and is not recommended as a mode of approach.

We now come to what we may term the normal modes of obtaining the cerebro-spinal fluid.

(1) Lumbar Puncture.

This is the commonest, simplest, and most useful method for routine withdrawal of the fluid. The spinal theca is entered through one or other of the interlaminal spaces, somewhere between the level of the second lumbar vertebra where the spinal cord ends, and the second sacral vertebra where the fluid-containing cavity of the spinal arachnoid comes to an end. The two widest interlaminal spaces are the third and fourth lumbar spaces. We usually select the fourth space, which, as a rule, is slightly the larger. To identify this space we draw a horizontal line at the level of the summits of the iliac crests; this line intersects the tip of the fourth lumbar spine. The patient is most conveniently placed on a rather low seat, stooping forwards, with his head between his knees and his knuckles touching the ground. In this posture the interlaminal spaces are separated to their maximal extent. Or, if the patient is in bed and unable to assume the foregoing posture, we make him lie horizontally on his left side with his hips fully flexed, so that the knees touch the chin. In an unconscious patient, and even in one who is delirious or violent, this may be accomplished by passing one loop of a roller-towel over the neck, then passing the far end of the roll (both layers) beneath the patient's flexed knees, and pulling them up towards his face. Or a strong stout portmanteau-strap may be used for the same purpose if we happen to be single-handed.

By means of iodine we carefully sterilise the skin in the region of our puncture, usually including an area which covers two or three consecutive interspaces. Then, having frozen the skin with an ethyl chloride spray, we make our puncture, using a fine platinum or nickel needle, which can be boiled without rusting. In a child we may enter straight in the middle line, but in the adult, in order to avoid the dense interspinous ligament, it is convenient to select a point about half an inch to the right of the middle line (if the operator is a right-handed person). We now push our needle horizontally forwards, converging towards the middle line. If we have selected our level accurately no bone is touched and the needle passes directly through the spinal muscles until it reaches the ligamentum subflavum between the laminæ. Through this ligament the needle passes easily with a characteristic sense of resistance and at once perforates the spinal theca which lies in immediate contact with the ligament. In a successful puncture, after the sense of resistance, we suddenly feel that the point of our needle is no longer opposed but in an open cavity. On withdrawing the stilette which fills the needle, the clear cerebro-spinal fluid at once begins to well out, drop by drop.

During this process one or two minor impediments may occur, for which we must be prepared. First, if our level is not quite accurate, or if the patient has osteophytes projecting from his spinous processes or laminæ, the point of the needle may strike a bone. It is no use trying to push forcibly through this; we would only bend or break our needle. The proper thing is to withdraw the needle slightly, change its direction of puncture to a level either slightly above or slightly below, and try again. Secondly, it may happen that although our needle has safely penetrated the ligamentum subflavum, no fluid comes out. This may be due to blockage of the needle by a tiny blood clot, or by a small plug of muscle or fibrous tissue; if so, these are easily cleared away by passing a stilette along the needle. Or again, the blockage may be due to one of the cauda equina roots having floated against the mouth of the needle; if so, by slightly rotating the needle the nerve-root will no longer obstruct it. Or it may happen that the needle has successfully pierced the ligamentum subflavum but has pushed the whole spinal theca in front of it, like the empty finger of a glove, without perforating into the arachnoid cavity. In this case, even although the needle is unobstructed, as shown by the stilette, no fluid comes. If this happens we must just withdraw our needle and start again at the space above or below.

We sometimes read of "dry punctures." This usually means, not that there is no fluid within the theca, but that the operator has failed to penetrate within its cavity. True absence of fluid is a very rare occurrence; it may occur, however, in cases where the theca in the region of the cauda equina is filled with blood clot or with tumour tissue.

It is hardly ever advisable to employ suction to induce the fluid to flow. Normally it exudes, drop by drop, at a moderate pressure of about 20 cm. of water in the horizontal posture. If the pressure is abnormally low, and there is no obstruction within the vertebral canal above, the intrathecal pressure can be temporarily raised at once by Quickenstedt's manœuvre. This consists in compressing the jugular veins in the neck, either by the fingers or by using the hollow air bandage of an ordinary sphygmomanometer.

Having secured the requisite quantity of cerebro-spinal fluid for examination (usually 5 or 6 c.cm. are enough) we withdraw our needle as gently as we had pushed it in, seal the skin puncture with a little collodion, and instruct the patient to lie down for eight or ten hours afterwards.

(2) Cistern or Suboccipital Puncture.

This method of approach is through the occipito-atlantal ligament, which stretches from the posterior rim of the foramen magnum to the corresponding part of the laminæ of the atlas vertebra. In this way we withdraw fluid directly from the cisterna magna. As can readily be understood, owing to the close proximity of the fourth ventricle which lies in the floor of the cistern, we do not adopt this route rashly or as a routine method of obtaining cerebro-spinal fluid. Like the honourable estate of matrimony, it is "not to be enterprized unadvisedly, lightly or wantonly, but discreetly, advisedly and soberly . . . ."

There are, however, some conditions in which cistern puncture is almost essential for completing a diagnosis; for example, in compressive lesions of the spinal cord, where we desire to compare the composition and pressure of the fluids above and below the level of compression; or again, for therapeutic purposes, when we wish to introduce curative sera into the cerebral arachnoid space, as in certain varieties of meningitis.

If you feel the back of your own neck, the highest vertebral spine to be made out is that of the axis or second cervical vertebra; the first or atlas vertebra has no spinous process. Immediately above the spine of the axis vertebra you will feel a depression. This is the spot where our needle enters in order to reach the occipito-atlantal ligament beneath which lies the cistern magna. The patient's head should be flexed towards the sternum so as to open out the occipito-atlantal space as much as possible. We find that the most convenient posture is the left lateral, except in cases where we desire to inject a heavy oil, such as lipiodol, into the cistern; in these cases we select the sitting posture. The needle enters in the middle line. It is pushed forwards and slightly upwards, penetrating the thick resistant ligamentum nuchæ. The correct plane of puncture is one which traverses the depression above the second cervical spine, the upper edge of the external auditory meatus, and the prominence of the glabellum. Seen in profile, these three points should be in the same straight line. (Fig. 1.) As we, of course, are standing behind the patient, we cannot see the glabellum, but we can easily identify the external auditory meatus by getting an assistant to place a pencil horizontally into the patient's ear. We then aim our needle at the level of the upper border of the meatus, keeping carefully to the middle line. The occipito-atlantal ligament is reached at an average depth in the adult of 4 to 5 cm. It is rarely more than 6 cm., although I can remember several athletic men with large cervical muscles in whom the distance was as much as 7 or even 8 cm. Our cistern puncture needle should be somewhat stouter than the lumbar puncture needle, so as to overcome the resistance of the ligamentum nuchæ without bending, and it should be fitted with a bevelled stilette. It should also be marked off in centimetres, so that we may know the exact depth to which it has penetrated.

Fig. 1.

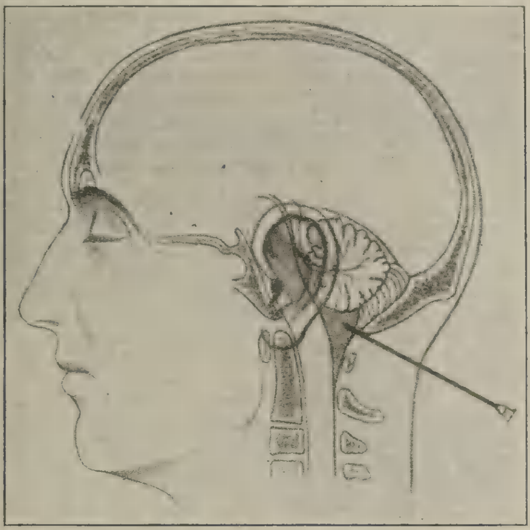

Diagram of cistern puncture.

In a successful cistern puncture, when we penetrate the occipito-atlantal ligament and enter the cistern, we feel a characteristic sensation of entering an open space, exactly similar to the feeling in a successful lumbar puncture. If the needle is wrongly directed it may strike too low, hitting the arch of the atlas, or too high, impinging on the occipital bone just behind the foramen magnum. This fault may be corrected by withdrawing the needle a short distance and trying again, carefully verifying the plane of puncture by means of the external auditory meatus and glabellum. On penetrating the occipito-atlantal ligament and entering the cisterna magna, cerebro-spinal fluid is at once obtained. If no fluid comes and we are certain that our needle is within the cistern, it may be that the middle lobe of the cerebellum is resting against the needle. But this is only likely to occur in two conditions: first, if our needle has been directed too acutely upwards; or secondly, in cases of increased intracranial pressure in which the cerebellum has prolapsed downwards towards the foramen magnum, forming part of a "pressure-cone." Such cases of intracranial pressure, however, can generally be recognised beforehand, and in them cistern puncture will be scrupulously avoided. In a successful cistern puncture we are careful to stop pushing in our needle the moment its point is within the cistern. The depth of the cistern varies from 1½ to 2 cm., which is our margin of safety, for it will be readily understood that if we are incautious and go too far, so as to reach the floor of the fourth ventricle, we might do grave and irreparable damage. In the hands of a skilful and careful operator, however, cistern puncture, although it sounds a hazardous procedure to those who have never witnessed it, is really easy and safe. In these wards you have all repeatedly seen it performed without difficulty and without discomfort to the patient.

(3) Ventricular Puncture.

This procedure, like cistern puncture, should be carried out with equal caution and reserved for exceptional cases. Sometimes it is of the utmost value, both for purposes of diagnosis and treatment. Thus, for example, in inflammatory affections, acute or chronic, of the nervous system, as in meningococcal, tuberculous, or syphilitic meningitis, it is important to compare the ventricular fluid with the subarachnoid fluid, whether derived from the cistern or from the lumbar pond. Again, in brain tumours, by withdrawing fluid from the lateral ventricle, replacing the fluid by air, and then taking radiograms of the air-filled ventricles, we can gain useful information not only as to the presence of internal hydrocephalus, but also as to the exact amount of distortion or displacement of the various cerebral ventricles. Further, in some inoperable tumours at the base of the brain, the headache and vomiting (symptoms which are due to internal hydrocephalus) can be promptly alleviated by ventricular puncture, which is a much less formidable affair than decompressive craniotomy. Some of you remember a patient in the ward a few weeks ago with a tumour of the pons in whom the agonising headache was at once relieved in this way.

In infants ventricular puncture can be carried out through the anterior fontanelle. In older patients, however, we have to penetrate the skull before reaching the dura mater. For this purpose Goetze has devised a steel drill which has a groove running along one side almost to its point. By means of this we quickly drill through the frozen scalp and skull until the point of the drill is through the inner table. We then pass a fine stilette along the groove into the brain. The drill is now withdrawn. A hollow blunt needle is next threaded on the stilette. Once this hollow needle is within the brain substance another blunt stilette, exactly filling it up, is inserted along the needle and the whole affair is cautiously pushed in, millimetre by millimetre, withdrawing our stilette from time to time to see when the ventricular cavity is reached, as shown by the welling out of clear cerebro-spinal fluid. The diameter of the ventricle in the line of puncture can be measured by first noting the depth at which fluid begins to flow, and then, on continuing to thrust in the needle to its far wall, noting the depth at which the flow ceases.

How do we approach the lateral ventricles in the adult skull? This can be done either from the vertex, from the side, or from the back of the head. The main cavity of the lateral ventricle is most conveniently approached from one or other side of the vertex, choosing a point 4 or 5 cm. in front of the upper end of the rolandic fissure. We may either do a vertico-internal puncture, entering our needle about 1 cm. from the middle line and directing it downwards and slightly outwards, or we may do a vertico-external puncture, which I find is rather more convenient, in which we select a point 4 or 5 cm. from the middle line and direct our needle downwards and inwards. (Fig. 2.)

To puncture the descending horn within the temporal lobe we take a line vertically upwards through the external auditory meatus or a little behind, and enter at a point a few millimetres above the upper edge of the pinna. In this case the needle is so directed that, when looked at from the front, it points towards the outer canthus of the corresponding eye.

The depth of a vertical puncture is somewhat greater than that of a temporal one; in the one case it is a few millimetres more, in the other a few millimetres less than the number of centimetres that go to the circumference of the head. Thus, in a skull that measures 65 cm., we expect to reach the normal ventricle at a depth of about 6·5 cm.

FIG. 2.

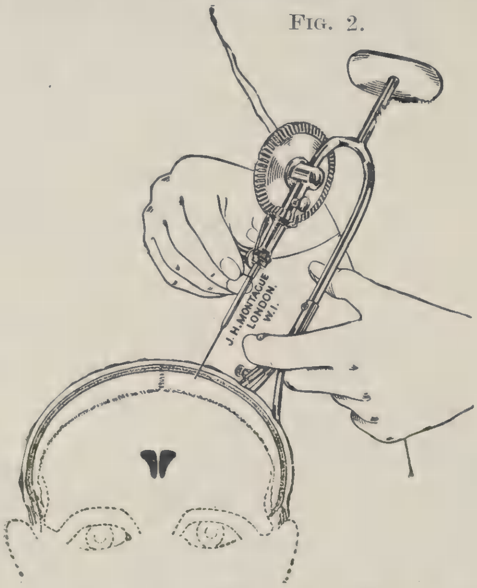

Diagram of ventricular puncture.

The posterior or occipital horn of the lateral ventricle is approached from behind. We select a point about ¾ in. above the superior curved line of the occipital bone and 1 in. from the middle line, and direct our needle horizontally forwards and slightly outwards.

Lewkowicz, of Krakow, who has done such valuable work on cerebro-spinal meningitis by studies on the ventricular and lumbar fluids, mounts his Goetze drill on a small electric motor such as is used ordinarily by dental surgeons. This, however, is difficult to carry about. Accordingly, I have devised a mechanical breast-drill with a multiplying action which has been made for me by Messrs. Montague, of 69, New Bond-street, W. This particular drill, as shown in Fig. 2, has an adjustable tripod base, whereby it can rest steadily on the convex surface of the head. It also has a movable sleeve on its shaft. This allows the drill-point rapidly to perforate the scalp and cranium and to stop short the moment we are through the bone. The stilette, followed by the hollow needle, blocked in its turn by the blunt stilette, are now passed through the drill-hole and pushed gently inwards until the ventricle is reached.

Contrary to what you might perhaps expect, ventricular puncture is almost painless, so that local freezing of the scalp is all that is required as an anæsthetic, even in the case of children.

The puncture mark on the scalp and cranium is only about the diameter of a large pinhole. As a matter of fact, within a few days after such a puncture it is impossible to detect any mark whatever, whether by the eye or on palpation of the patient's head. If we wish to do a subsequent puncture it is necessary to make a fresh drill-hole.

DIABETES AND OPERATION.

A NOTE ON THE EFFECT OF GASTRO-JEJUNOSTOMY UPON A CASE OF MILD DIABETES MELLITUS WITH A LOW RENAL THRESHOLD.

By O. LEYTON, M.D. CAMB., F.R.C.P. LOND.,
PHYSICIAN TO THE LONDON HOSPITAL.

As a rule the publication of a single case, however rare, needs justification; in this instance it is not the case but the observations made upon it that make publication advisable.

Duodenal ulcer is not uncommon in diabetes mellitus—one condition does not protect from the other—but it is rare to meet it in a patient suffering from so mild a degree of diabetes as to make operation advisable. A general anæsthetic usually makes the diabetic condition much more grave. The change need not necessarily be sudden or dramatic, and therefore often fails to be recognised. Duodenal ulcer in a man with mild diabetes and a low renal threshold must be very rare, and so I publish the single case.

Diabetes mellitus is diagnosed, as a rule, by the glycosuria accompanying it. Diabetes mellitus is an unfortunate term, it is like "exophthalmic goitre," the name of the disease denotes the two most obvious signs. To say that one has met diabetes mellitus without the patient suffering from glycosuria sounds a contradiction in terms, but is no greater a contradiction than "exophthalmic goitre" without exophthalmos or goitre.

When one starts thinking about diabetes mellitus with a gradual onset one must realise there is a stage at which the patient's powers of burning and storing sugar have fallen from the normal 100 per cent. to 95 per cent., and that the deterioration may be very slow. In my opinion this gradual deterioration often is suddenly accelerated by some injury to pancreatic cells or by infection, and then the diagnosis of diabetes mellitus is made. The difficulty remains, however, that a man with only a 75 per cent. efficient carbohydrate metabolism will be able to eat and drink ordinary food without glycosuria occurring, provided his renal threshold for sugar is normal. In other words, he would be suffering from diabetes mellitus without glycosuria (hypoglycopyresis).

This avenue of investigation has not been explored very fully, and yet it may lead towards the origin of diabetes mellitus in middle life. The case I am recording had a very mild diabetes, his glycopyretic function was of 75 per cent. efficiency, and it seems unlikely that diabetes would have been diagnosed if he had not possessed a remarkably low renal threshold for sugar. At one time his urine contained quite a recognisable quantity of dextrose, whilst his blood-sugar was below 0·12 per cent. (many individuals do not have glycosuria until their blood-sugar reaches 0·21 per cent.).

Clinical Record.

T. M., aged 37. Admitted to hospital May 26th, 1924. He gave a history of being quite well until three years ago, when he began to have attacks of abdominal pain lasting for two or three hours, usually two or more hours after food. Occasionally he had free intervals of three to six weeks. Taking food relieved the pain. His appetite was good. The pain started in the epigastrium and ran round to the back, sometimes kept him awake at night, at other times awakened him in the early morning. Six months ago sugar was found in the urine. The patient, upon interrogation, admitted very slight thirst occasionally and cramp in the legs, but neither of these seemed to be sufficiently intense to suggest diabetes mellitus. The patient was placed upon a diet of 1660 calories containing 44 g. of carbohydrate, 78 g. of protein, and 130 g. of fat, and whilst on this diet his urine contained a small amount of sugar, whilst his blood-sugar was found to be 0·09 per cent. one hour after the mid-day meal. This suggested that his renal threshold for sugar was low. He was given 25 g. of dextrose and it was found that his renal threshold was below 0·11 per cent.

I decided to see the effect of a meal rich in carbohydrates, and on June 6th he was given a lunch containing as much meat and vegetable as he liked, along with a large helping of suet pudding and plenty of syrup. Samples of blood were taken at intervals of 20 minutes; at 2.10 P.M. his blood-sugar was found to be 0·30 per cent., it rose to 0·33 per cent., where it remained until 3.25 P.M., then it fell to 0·30 per cent., and was still 0·30 per cent. at 4.40 P.M. This was evidence that he was suffering from mild diabetes.

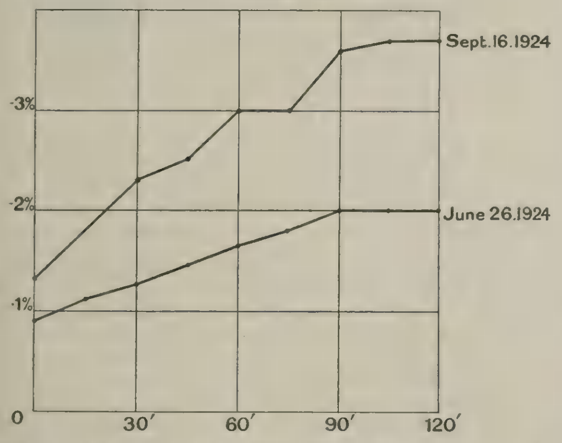
On June 17th he was given 75 g. of dextrose by the mouth at 1 P.M. An hour later his blood-sugar was 0·30 per cent.; 90 minutes after the dose it rose to 0·38 per cent. and had dropped to 0·18 per cent. three hours after the administration of the dextrose. This observation was corroborative evidence that the patient was suffering from diabetes mellitus, based not only on the excessive rise, but also the fact that after three hours the blood-sugar was double the normal fasting. Since the history left no doubt that he had duodenal ulcer as well, it seemed advisable to determine the efficiency of his carbohydrate metabolism before submitting him to operation. On June 24th he was given an intravenous injection of a 10 per cent. solution of dextrose at the rate of 1 c.cm. per minute for three hours. His blood-sugar started at 0·10 per cent. and did not rise above 0·14 per cent.; obviously the dose of sugar was too small to exercise fully the sugar-burning and storing function.

Therefore another intravenous injection had to be given. On June 26th a 20 per cent. solution of dextrose was injected intravenously at the rate of 3 c.cm. per minute for two hours. The blood-sugar started at 0·08 per cent. and rose to 0·20 per cent. after 90 minutes, where it remained for the following half hour. (Chart 1.) This curve proved, since it did not rise above 0·2 per cent., that the patient was able to store and burn sugar at the rate of nearly 0·6 g. dextrose per kilo body-weight per hour, instead of 0·8 g. dextrose per kilo body-weight per hour, which is considered to be normal. In other words, his carbohydrate metabolism proved to have an efficiency of 75 per cent. In the near future I shall offer the further interpretation of this curve along with many others of a similar type.

Operation.—The patient was then transferred to the surgeon. An ulcer was found on the anterior surface of the duodenum; the gall-bladder was thickened; a posterior gastro-jejunostomy was performed; the appendix was looked at, but not removed. The patient made an uninterrupted recovery. Was fed on Benger's food, and later upon custard, jellies, milk pudding, bread and butter, and fish.

The day after the operation the urine contained a considerable quantity of sugar, this gradually diminished, until the eighth day, when it was free. The urine remained sugar-free until the twenty-second day, when minute traces reappeared, but was quite free again later. The patient left the hospital on July 29th, 1924, free from pain and apparently greatly improved.

CHART 1.

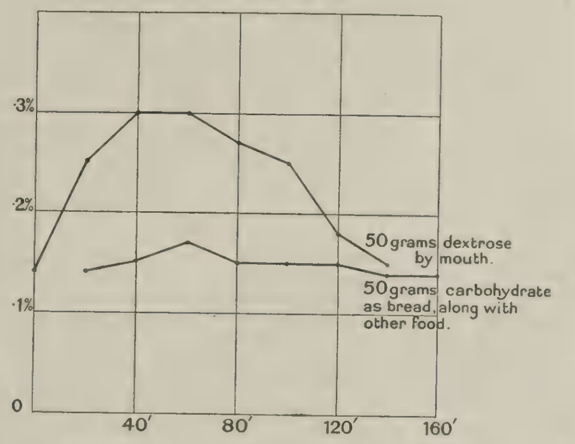


The question arose as to how far the operation had raised or depressed his sugar-burning capacity. Was the apparent improvement due to gastro-jejunostomy delaying absorption? On Sept. 16th intravenous injection of a 20 per cent. solution of dextrose was given for two hours in a manner exactly similar to the injection of June 26th. It was found that his blood-sugar rose to 0·37 per cent. after two hours instead of 0·2 per cent. There was loss of sugar in the urine at least equal to that during the previous intravenous injection. This observation proved that the patient's carbohydrate metabolism had been depressed by the operation. (See Chart 1.)

How can we account for the apparent improvement? The glycosuria was absent after operation in spite of a diet containing a fair amount of carbohydrate. In order to determine whether the operation had interfered with rate of absorption and also raised the renal threshold for dextrose the following observations were made.

On Sept. 20th the patient was given 50 g. of dextrose at 10 A.M., after he had had breakfast. His blood-sugar started at 0·22 per cent. and rose to 0·3 per cent. after 60 minutes and fell to 0·13 per cent. after 120 minutes. On Sept. 22nd he had breakfast at 9.30 A.M., two poached eggs on toast, cup of coffee and milk, 2 oz. of bread; the carbohydrate content of this meal was approximately 50 g. His blood-sugar did not rise above 0·17 per cent. after that meal, the highest being reached at 60 minutes, and later on the same day a second observation was carried out; 50 g. of dextrose was given at 2.5 P.M. His blood-sugar started at 0·13 per cent., rose to 0·3 per cent. after 40 minutes, and fell to 0·15 per cent. after 140 minutes (Chart 2).

CHART 2.



I think from this observation we may reasonably conclude that his power of absorbing starch had been diminished, and also from the fact that in spite of his blood-sugar rising to the region of 0·15 per cent. after an ordinary breakfast, and his urine, as a rule, being sugar-free, his renal threshold had been raised.

The operation in this case, as in many cases, led to the progress of the disease, due to the administration of an anæsthetic. In my experience it is extremely rare for a general anæsthetic, other perhaps than nitrous oxide and oxygen, not to lead to a definite deterioration of the carbohydrate metabolism in cases of diabetes mellitus.

WELLCOME HISTORICAL MEDICAL MUSEUM.—The museum, at 54A, Wigmore-street, London, W., will be closed for alteration and reorganisation from Dec. 1st until the end of May. Since the foundation of the Wellcome Historical Medical Museum in 1913, there have constantly been additions of important historical objects acquired by purchase, donation, and permanent loan. The growth of the collections has been so great that extensive alterations in the museum and a complete rearrangement of the exhibits have become necessary. The reorganisation will be of such a thorough character that the Director, Mr. Henry S. Wellcome, has decided to close the institution for several months. Although this may cause temporary inconvenience to medical and other scientific research workers and students, the change, when effected, will prove of great advantage by rendering the arrangement and classification more systematic, and the objects more accessible for inspection and study. Important additions have been made recently to the technical staff. Mr. L. W. G. Malcolm, M.Sc. Camb., F.R.S.E., who has gained distinction in the field of anthropology and allied sciences, has been appointed conservator. Mr. Charles R. Hewitt, who for 22 years was connected with the library of the Royal College of Surgeons of England and 13 years librarian of the Royal Society of Medicine, has been appointed chief librarian.

A MULTIPLE ELECTRICAL STETHOSCOPE.

By JENNER HOSKIN, M.D. Camb.,
ASSISTANT PHYSICIAN, ROYAL FREE HOSPITAL.

The instrument on which my investigations have been made is the outcome of a large number of experiments, whose aim has been to provide the means of increasing the intensity of sounds produced within the heart and lungs without distortion, and of enabling several persons to listen to them simultaneously.

Historical.

Cabot[1] devised a mechanism whereby, with the aid of levers tapping on drums and of organ-bellows connected with a megaphone, the sounds of the heart and lungs could be imitated, and demonstrated it before the American Medical Association at Boston in 1906. Normal heart sounds and murmurs were transmitted electrically and recorded graphically by Einthoven [2] in 1907. In 1910 Brown [3] reproduced heart sounds by a tuned mechanical relay, consisting of a single microphonic contact and an electro-magnetic element. The sounds were transmitted audibly, but with a considerable degree of distortion, over a commercial telephone line in London.

The earliest developmental work on electrical stethoscopes was centred about the carbon transmitter and other microphonic contact devices. Williams [4] was the first to make use of an electro-magnetic transmitter, and in 1921 with this type of transmitter and a two-stage amplifier he secured more accurate graphic records of murmurs. In the same year Squier,[5] using a carbon transmitter amplified normal heart sounds to a group of physicians. In 1923 Abbott,[6] by means of a transmitter, tuned to exclude all sounds except those of very low frequencies, amplified heart sounds and distributed them through a loud-speaker, as did Jacobsohn [7] about the same time in Berlin. The present instrument is, however, largely the result of the experiments of Cabot and Gamble [8] at the Massachusetts General Hospital and their coöperation with the Western Electric Company, who have designed it to their requirements. A multiple electrical stethoscope was first used by them for classroom lectures in 1923.

Description of Instrument.

The instrument used by me, which is a further improvement on that of Cabot and Gamble, consists of the following main parts, assembled in a portable cabinet about the size of a tea-wagon : (1) an electromagnetic transmitter ; (2) a three-stage amplifier ; (3) a series of electrical filters ; (4) a number of output receivers ; (5) one six-volt storage battery and one 130-volt " B " battery.

The *electromagnetic transmitter or microphone* is equipped with a special vibratory element, which is placed in direct contact with the patient's skin. It is insensitive to air-waves, and is provided with a special hand grip to prevent the vibrations of the operator's hand from causing undesirable noises. Owing to the high magnification of the sounds necessary, it has been found impossible to use a carbon transmitter or microphone, as the loose contacts introduce a certain amount of noise, which, when amplified along with the faint sounds of interest, tends to obscure them. This is known as the microphone roar, and cannot be eliminated.

The electromagnetic transmitter requires a more powerful amplification, but in a great measure gets rid of this noise. The *three-stage amplifier* employs resistance coupling between the first and second stages, and transformer coupling between the second and third stages, using two high impedance vacuum valves for the first two stages and a low impedance or " power " valve to furnish an adequate energy output in the third stage. This amplifier is capable of a power amplification of 100 million times, corresponding to an increase in intensity over the reproduction amplitude of the ordinary Bell's stethoscope of over 1000 times. There is a potentiometer between the first and second valves, which makes it possible to increase the amplification by small steps, each step giving twice the amplitude of the preceding one.

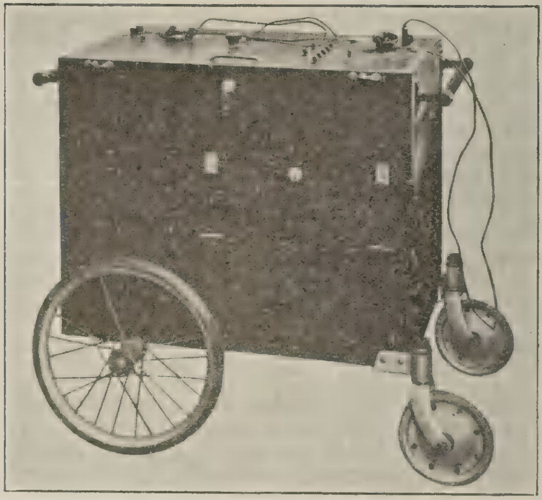
A preliminary analysis with *electrical filters* of sounds of clinical interest tended to show that these were composed largely of frequencies below 1000 cycles, and as the sound frequencies differed widely, it was found of great advantage to permit concentration on any given sound by the use of electrical filters. The function of filters is to allow sounds of certain frequencies to pass and to cut off those of other frequencies.

There are three types of filters—low-pass, high-pass, and band-pass. Low-pass filters allow currents below a particular cut-off frequency to pass freely, at the same time diminishing very considerably the transmission of those of higher frequency. High-pass filters do the opposite. A low-pass filter and a high-pass filter connected in series constitute a band-pass filter, which only allows the passage of currents of a certain range of frequencies.

The instrument has five filters whose cut-off frequencies have been based on 100 hospital cases of cardiac and pulmonary conditions. They are as follows : Low-pass, 130, 400, 650, 1100 ; high-pass, 130.

For example, the use of a low-pass 400 combined with a high-pass 130 would constitute a band-pass filter permitting the exclusive passage of frequencies between 130 and 400 cycles.

The *output receivers* are on the principle of those of the telephone, and consist of an electromagnetic diaphragm provided with a special cap and nipple, which is designed to fit the tubing of the binaural stethoscope in place of the ordinary chest-piece. Each receiver is provided with a spring clip for attachment to the observer's clothing, so as to leave both hands free for manipulating the control switches of the amplifier and filters. There are ten receiver-jacks, through which any number of receiver circuits up to ten may be connected. The receivers are connected in parallel in the output circuit, so that the volume of sound tends to decrease with the number of receivers in use. A volume control switch, however, is provided for maintaining efficient reproduction, whatever the number of receivers connected in the circuit.



The Multiple Electrical Stethoscope.

Special Uses of the Instrument.

My investigations have been directed to the following uses of the instrument : (1) Examination of the fœtal heart in the later stages of pregnancy. (2) Value of the instrument for ordinary teaching purposes. (3) Value for bedside demonstration of cardiac cases too ill to permit individual examination by a number of students. (4) Diagnosis of difficult heart cases. (5) Value for investigation of pulmonary conditions.

The amplification of the sound is controlled by the moving of a hand along the periphery of a circular disc, marked with the numbers 1 to 22, each number approximately doubling the amplitude of the preceding one. It was found that, when the filters were not in use, the intensity equalled that of the ordinary Bell's stethoscope when the hand was pointing to 8 or 9, but when the filters were in use the hand had to be advanced up to 11 or 12 to obtain the adequate volume of sound.

I investigated the fœtal heart sounds in the later months of pregnancy in a few cases. The fœtal heart could be heard distinctly using the low-pass filter with the hand of the amplifier about 15 to 18, and on advancing the hand still further the intensity of the sounds could be increased to an almost overwhelming degree. A sound which was probably the placental souffle could also be heard, and investigations are being made with a view to the possibility of diagnosing the position of the placental site by this means. Without the filters there was a tendency to "roaring," especially with high amplification.

The normal heart sounds are best heard with the low-pass 130, which cuts off most of the murmurs and pulmonary sounds. This filter, however, allows the sounds of a bass or baritone voice to pass. The low-pass 400 is useful for distinguishing presystolic murmurs and certain low-pitched systolic and diastolic murmurs. The low-pass 650 seems to be the most useful of all the filters for heart murmurs, as the majority are of frequencies below this. The low-pass 1100 brings out a few of the very high-pitched murmurs and high-pitched râles, but its usefulness is impaired by the amount of external noise which becomes audible when the higher frequencies are allowed to pass. The high-pass 130 has been found extremely useful in conjunction with the low-pass 400 and with the low-pass 650, especially with the latter. This has the effect of greatly diminishing the intensity of, whilst not obliterating, the heart sounds themselves, and so enabling a more thorough concentration on the murmurs. In general, the low-pass 130 has been found the best for the examination of fœtal heart sounds and for distinguishing alterations from the normal of the ordinary heart sounds. The low-pass 400 appears the most efficacious for distinguishing presystolic murmurs. Their determination is rather a matter of accuracy of timing than of hearing, and so it is of advantage to allow the full passage of the heart sounds. For distinguishing aortic diastolic murmurs the band-pass filter formed by low-pass 650 and high-pass 130 has been found to be the most useful.

My investigations have been mainly directed to the heart, but a few pulmonary conditions have been examined. I have been somewhat disappointed with the instrument in this connexion, as the breath sounds appeared to be so altered in pitch and character by the different filters as to make the differentiation of the various types of breathing difficult and uncertain, whilst without the filters it is difficult to separate the external sounds from those in the chest. I feel, however, that further investigation with the instrument in pulmonary conditions is necessary before forming a definite opinion as to its usefulness for this purpose.

The instrument has a definite though limited use in teaching beginners to recognise heart sounds and murmurs. Frequently they take a considerable time to become conversant with what they hear on listening to a heart, and the increased amplitude and the separation of the sounds and murmurs by means of the filters may tend to help them in their early training in auscultation. For more advanced students the instrument has been found satisfactory for the purpose of demonstrating cases in which the interest is centred in the auscultatory phenomena, in that without any external connexions ten persons are able to listen simultaneously, and the teacher can demonstrate the interesting points as they arise.

For diagnostic purposes the electrical stethoscope has, in my opinion, a definite sphere of usefulness as a means of bringing out slight changes in the heart sounds and facilitating the recognition of very faint murmurs such as may be present in some cases of aortic regurgitation. In the bedside demonstration of cardiac cases who are seriously ill the fact of having ten receivers avoids a great deal of the discomfort and fatigue that would ensue through examination by several persons.

There is one point which should be mentioned. In order to obtain the best results very careful adjustment both of the degree of amplification and of the filters is required, and the process of examination, therefore, tends to be a good deal more lengthy than with the ordinary binaural stethoscope.

Suggestions.

There is, in my opinion, room for improvement in diminishing the external noises, which become audible with the higher amplifications. An additional low-pass filter designed to cut off all frequency cycles above 100 would be of great value, both from the point of view of differentiating especially low-pitched murmurs and also for the purpose of eliminating all ordinary voice sounds. This might advantageously replace the low-pass 1100 filter, which has been found to be of very little practical value.

Conclusions.

The multiple electrical stethoscope has, in my opinion, a definite field of usefulness for diagnostic and teaching purposes both in the realms of medicine and obstetrics. I consider, however, it would be a mistaken policy to train students to place undue reliance on the instrument for the following reasons:—

1. It is of the highest importance that their clinical experience should be gained with the ordinary stethoscope, on which they must necessarily rely later on in the course of their practice.

2. In using the multiple stethoscope attention is naturally concentrated on auscultation, which constitutes only one, and in my opinion one of the less important methods whereby a cardiac case is investigated.

My investigations have been made at the Royal Free Hospital with an instrument presented to the hospital by Lord Riddell, its President, of whose generosity I wish to make grateful acknowledgement. I should like to express my indebtness to Dr. A. G. Phear, senior physician to the hospital, who has given me the benefit of his experience both in my investigations and in the writing of this paper. I should also like to thank Mr. Bulloch and other members of the Western Electric Company for the help they have given me in the technical details of the instrument.

Clinical and Laboratory Notes.

A CASE OF ACHOLURIC JAUNDICE WITH GALL-STONES.

BY H. H. GLEAVE, M.B. LEEDS, M.R.C.P. LOND.,
ASSISTANT PATHOLOGIST, ROYAL INFIRMARY, SHEFFIELD;
AND
ROBERT PLATT, M.D. SHEFF., M.R.C.P. LOND.,
MEDICAL REGISTRAR AND BIOCHEMIST TO THE INFIRMARY.

CASES of acholuric jaundice, complicated by gall-stones, are rare, and the following seems worthy of record.

B., a man of 42 years, had been operated on 15 years ago at St. Mary's Hospital for gall-stones. He was jaundiced at that time. Cholecystostomy was performed, and he was told that he had a large spleen. Since then his skin has always been of a yellowish tinge, and there is a history that his mother's skin was also yellow. He had no further trouble, however, until August, 1923, when he had a typical attack of biliary colic. In August, 1924, he had another attack, and became very deeply jaundiced. He was then seen by Mr. R. St. L. Brockman, of Sheffield. The spleen was still enlarged, and a diagnosis of acholuric jaundice was made, but since the immediate cause of the symptoms was obviously a calculus, Mr. Brockman operated and removed a pigment stone from the ampulla of Vater. There was considerable difficulty in finding the stone, owing to adhesions from the previous operation, and to remove the spleen at the same operation would have been too risky an undertaking. The patient made an uninterrupted recovery, and although he felt very much better, the jaundice never disappeared. The Van den Bergh reaction was therefore done, and showed that the remaining jaundice was of non-obstructive type.

In April, 1925, the case was seen by Dr. A. E. Barnes and Mr. Ernest Finch, and some further tests were done (see later) confirming the diagnosis of acholuric jaundice. On May 15th, 1925, Mr. Finch and Mr. Brockman removed the spleen, one of us (R. P.) performing a blood transfusion while the wound was being stitched up. He again made an uninterrupted recovery, and his jaundice had disappeared within ten days of the operation. He is now feeling very fit in every way (December, 1925).

Observations: Blood Tests Before and After Operation.

—	1/5/25.		Operation (splenectomy) 15/5/25.	29/5/25.	
Red cells .. .. .. Hæmoglobin .. .. Colour-index	3,250,000 67 % 1·03			4,470,000 89 % 0·99	
Blood group	III.			—	
Van den Bergh reaction. (Direct test always negative.)	15 units.			0·7 units.	
Blood cholesterol ..	—			0·18 %	
Hæmolysis to NaCl	Patient.	Control.		Patient.	Control.
Initial. .	0·525	0·425		0·6	0·575
Marked	0·450	0·40		0·525	0·45
Complete	0·425	0·375		—	—
Hæmolysis to saponin	—			Normal (same as control).	

The urine before operation contained a large excess of urobilin.

Report on Pathology and Histology of Spleen.—Naked eye: A large firm spleen, weight 23 oz.; dimensions 7 in. × 5 in. × 1½ to 3 in. A small accessory spleen (about the size of a walnut) was attached at the hilum. About a quarter of the diaphragmatic surface showed signs of adhesions with great thickening of the capsule. There is extreme congestion

Microscopical: There are numerous thick fibrous septa. The Malpighian bodies are present, undoubtedly reduced in size and number. The supporting framework of the capillaries and endothelial cells of the pulp is unusually prominent. There is extreme congestion.

No foci of hæmopoietic tissue are to be seen. There is much brown pigment, giving the reaction of ferric salts ("hæmosiderin"). This is almost entirely confined to the pulp and hardly appears at all in the fibrous septa, capsule, or Malpighian bodies. It is seen chiefly as a diffuse brown staining (green with the Prussian blue reaction) of the endothelial cells forming the reticulum of the pulp. These cells have often delicate branched processes of cytoplasm which, like the body of the cell, are also pigmented, and in some cases the wall of a sinus or capillary is completely formed by such pigmented cells. In some cells, especially mononuclear cells lying free in the pulp, the pigment is seen as discrete granules or in masses distending the cell.

The general picture is that of hyperplasia of the reticulum cells, with deposition of iron pigment to a much greater extent than in health, though not to the degree seen in some cases of pernicious anæmia.

Discussion.

Cases such as the above, though rare, are by no means unknown.[1] Since hæmolytic jaundice differs from obstructive jaundice in that the blood cholesterol instead of being increased is actually lower than normal,[2 3 4] it is interesting to note that the calculus removed at the first operation was a pigment calculus. In some of these cases such calculi have been found to contain no cholesterol whatever.[5] Unfortunately we did not have the opportunity of examining this one. The blood cholesterol was only estimated after the splenectomy, and was found to be normal. A sharp rise after removal of the spleen is apparently the rule in these cases.[2]

In spite of the operation, at which very little blood was lost, the blood count was better a fortnight afterwards than it had been before. (This has, however, been recorded in a case without transfusion.[1]) The transfusion was performed with 450 c.cm. of defibrinated Group IV. blood, by a method modified from that of Colebrook and Storer,[6] no citrate whatever being added. It was the ninth transfusion of a series which has now reached 28, in which defibrinated blood has been used. In none of the 28 cases has there been any reaction following the transfusion, such as occurs in many cases with the citrate method.

The Van den Bergh reaction is of rather exceptional interest. The first test, done soon after the gall-stone was removed, gave a delayed bi-phasic reaction, presumably because some obstructive jaundice still remained, and the indirect method gave a reading of 15 units. The two subsequent tests gave an indirect reaction only, the reading falling from 15 to 0·7 units within a fortnight of splenectomy.

The resistance of the red cells to hypotonic saline was slightly decreased, and remained so after the operation. Most observers report a return to normal after splenectomy,[7 8] others, as in our case, have found no alteration.[2 9] The resistance of the corpuscles to saponin was tested in view of the suggestion of one of the authors (R. P.[10]) that it might on theoretical grounds be increased while the resistance to saline was decreased. In this case it was normal to saponin. Since doing the tests we find that others have found the resistance lowered in acholuric jaundice to both saponin and saline.[11]

The usual histological findings in the spleen of acholuric jaundice are deposition of iron-containing pigment, and distension of the sinuses by red cells.[12 13] In the present case there is also evidence of hyperplasia of the cells of the reticulum.

We are indebted to Mr. Finch and Mr. Brockman for permission to publish this case.

A CASE OF
RUPTURED ECTOPIC GESTATION.

By Elaine Knowles, M.B. Leeds, M.R.C.S. Eng.,
RESIDENT GYNÆCOLOGICAL OFFICER, LEEDS GENERAL INFIRMARY.

This case of ruptured ectopic gestation is of interest as it occurred in an unmarried girl of 18, with no definite history of pelvic inflammation.

The patient was admitted into the Leeds General Infirmary under the care of Mr. Carlton Oldfield on July 4th complaining of great pain in the lower abdomen, particularly on the left side, and of great weakness and thirst.

History.—The menstrual period began at 13, and had always been regular, the onset being every fourth Friday night or Saturday morning, the first few hours being accompanied by a slight dragging pain in the left iliac region. The loss was not excessive, and lasted 4–5 days.

Present Illness.—On Sunday, June 21st, the period began one day late, and continued, though the loss was very slight, until Sunday, June 28th. On that day she had an attack of pain, dragging in character in the left iliac region, and lost quite profusely for about half an hour. Similar attacks occurred daily until July 3rd, when at 9 A.M. in the morning the pain came on suddenly and with great violence, but was not accompanied by bleeding. It was relieved by "a pill," but returned at 7 P.M., and continued until admission, spreading over the whole of the lower abdomen. Vomiting occurred once on July 3rd after eating a biscuit. Patient never fainted, but felt very weak. She had exposed herself to the risk of pregnancy a month before the onset of symptoms.

Condition on Admission.—Temp., 97° F.; pulse, 120; resp., 27. The patient was very pale, the mucous membranes being practically colourless. Abdominal examination: the abdomen moved very little on respiration. Palpation: great tenderness and rigidity over left half of lower abdomen, much less over right half. Percussion: dullness over left lower abdomen extending little way across middle line.

Pelvic examination: the uterus was slightly enlarged, the cervix a little soft and patulous, the external os admitting the tip of the little finger. No bleeding occurred per vaginam. There was great tenderness in left fornix, with a feeling of fullness, but no definite tumour was felt. A diagnosis of ruptured ectopic gestation was made.

Operation.—Laparotomy was performed by Mr. H. W. Symons, of this hospital. On opening the abdomen the peritoneal cavity was found to contain much free blood and some blood clot. Brisk hæmorrhage was taking place from the left tube, which was ruptured in the inner third of the ampullary portion. Left salpingectomy was performed. Left ovary and right tube appeared normal. Right ovary contained a small cyst. All blood clot and free blood was removed from the peritoneal cavity. The ovum was not discovered. The abdomen was closed.

The *pathological report* on the tube made by Miss E. M. Hickman, M.D., was as follows: Typical decidual tissue and very early trophoblast are present with some hæmorrhage. The wall of the tube shows some lymphocytic infiltration.

The patient made an uninterrupted recovery and returned home on July 13th.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF MEDICINE.

A MEETING of this Section was held on Nov. 24th, with Dr. HUGH THURSFIELD, the President, in the chair.

Prof. H. MACLEAN opened a discussion on

Nephritis.

He said that the old division of this condition into "acute" and "chronic" was the best. The kidney was chiefly an organ for the elimination of water, salts, and waste products. In acute nephritis all its functions were suspended. In the chronic case only one important function was suspended—viz., the elimination of the waste products of nitrogenous metabolism; the organ was able to deal with water and salts. There was no such thing as "chronic parenchymatous" nephritis; either the patient recovered from his acute disease (which was not very common) or he died, or else he passed into a low form of the chronic interstitial nephritis. The books gave different descriptions because the patient was described at different stages. In a typical case of parenchymatous nephritis the one phenomenon present was the large accumulation of fluid; the patient was waterlogged. But the kidney could excrete nitrogenous proteins quite well—the urine was full of them. The clinical picture was one of excessive œdema with albuminuria. When the kidney passed into a state of chronic nephritis it regained its power of excreting water and salts and lost the power to excrete nitrogenous products. A waterlogged patient with vomiting was sometimes diagnosed as a case of uræmia; the vomiting was perhaps due to the fluid, but it was certainly not uræmic. A parenchymatous patient would seem to improve, feeling better and losing some of the fluid, but the change might be really for the worse as he was passing into the chronic condition. In determining the nature of such a case the tests used were helpful.

Urea Estimations.

There was no sense in the elaboration of tests practised in some places; quite as much information was gained from two simple ones—the estimation of blood-urea and of the urea concentration in the urine. For the practitioner the latter was the more important. A high blood-urea was not uncommon in conditions which were not renal at all, but much information could be got from knowing the amount of urea that the patient was capable of excreting under ordinary circumstances. Albumin in the urine was not important except as a hint that there might be something wrong. Albuminuria might be a most serious feature or might mean nothing at all; variations in the amount were not significant except that great variation was not usually found in serious cases. In estimating the urea concentration there was no need to take a 24-hour specimen. The concentration was the important thing, not the total amount. A nephritic case passed a lot of urine in the night when the normal person would not pass any and so might get rid of much the same total amount of urea as the normal person. In doing the urea test the most important point was to starve the patient of fluid for 12 to 15 hours before giving the 15 g. test-meal of urea. Quite often after the period of fluid starvation the urine voided before the test began would be found to contain 3 per cent. of urea, in which case no further testing was necessary. Elaboration of the tests was not only useless but also produced something of a mutiny among the patients.

Treatment.

The best diet for the case of acute nephritis was still debatable, but there was no point in giving large amounts of milk to reduce the protein; it was doubtful, in fact, whether protein did great harm. A small amount of protein could be given with advantage, the main diet being carbohydrates. It was no good trying to "wash out the kidney." The essential feature of the disease was the failure to excrete water, and the kidneys would not wash out, in spite of all the facilities already provided by Nature, such as high blood pressure and a lot of urea in the blood. Urea was one of the best diuretics known, and the addition of another diuretic would not help. It was cardiac œdema that benefited from diuretics. Sooner or later Nature would bring on a diuresis in the renal case, and if this happened to coincide with the administration of some diuretic drug it might be attributed to that drug. The symptoms must be treated as symptoms. The general impression that protein was detrimental to the kidney had been overdone, and many cases did very much better with a fairly liberal amount of protein. Many a patient who failed to improve was really suffering from his treatment—the low, sloppy diet given him. A certain amount of work had been done in America and Germany on the reaction of the kidney to protein, and Prof. MacLean had repeated the experiments. Rabbits fed on protein diet only showed albuminuria and casts and developed apparently a nephritis, but if the rabbit were given the smallest amount of green food along with the protein diet there would be no bad result at all. It seemed clear that it was lack of green food—and probably of the vitamins in it—and not the administration of protein that damaged the kidney. When the symptoms had been established they could be stopped by the addition of green food. There was therefore no experimental evidence that protein was deleterious to the kidney, nor was there much real clinical evidence for the deleterious effect of proteins in an ordinary mild case of nephritis. In acute parenchymatous cases some treatment by drugs or physical means was necessary to get rid of the fluid. On the whole, physical means were better, but large doses of urea helped, as did a diet rich in protein. There was some evidence from America that ammonium chloride in 5–15 g. doses thrice daily for a couple of weeks would sometimes clear up these œdemas, but the difficulty was to distinguish between real reaction to the drug and the coincidence of the natural tendency to get rid of fluid at some stage of the disease.

Prognosis.

Better than clinical evidence was the result of the blood-urea and urea-concentration in the urine tests. It was possible to have a patient with no symptoms at all who was yet bordering on uræmia. While blood pressure and cardiac changes were often associated with renal disease, each might occur independently. The outlook in the cardiac case was bound up with the question of whether or not the kidney would become affected; if it escaped for a few months the prognosis was not bad, but the physician should be very cautious until he had had the patient under observation for at least six months.

Discussion.

Dr. Langdon Brown agreed cordially with what Prof. MacLean had said, and especially welcomed the release from the tyranny of elaborate tests. At a discussion on nephritis 15 years ago he had said that the conventional views might be summed up as restriction of the protein intake, knowledge of the total output of urea in 24 hours, flushing out the kidneys, and the attempt to get elimination through the skin, and he had expressed his belief that every one of these was largely based on error, and should not be regarded as the criteria for the diagnosis, prognosis, and treatment of nephritis. The false idea that albuminuria could be affected by restriction of the protein in the diet was based on some early experiments of Sir D'Arcy Power, who had found an albuminuria in himself after eating a number of eggs. But he had also rowed a course, and the albuminuria he had had was merely the functional albuminuria of adolescence. As a result every nephritic patient had been since told that he must not eat eggs! Patients should not be filled up with proteins, but neither should they be starved of nitrogen, except perhaps in the acute cases. He had used van Noorden's diet, and found patients do well on nothing but fruit-juice and sugar. The urea excreted came from the food, so if the protein was cut down because the urea excretion was low the patient, receiving less and less urea, naturally excreted less until he either became worse or revolted against his treatment. There was a stage in which the hydræmia passed into a failure to excrete things for which the kidney had a threshold. The hot air bath might be a great help. The sweat had been found to contain a great deal of sodium chloride; the removal of the salt caused a reduction of the amount of water retained in the tissues, and the diaphoresis was followed by a daily diuresis. The bath, however, might be dangerous to those who had not much œdema. It must be remembered that although the blood urea was a valuable test, the other and unknown nitrogenous bodies constituted the toxic factor. The proportion of these to urea was not the same in disease as in health. His house physician had had a theory that the administration of hydrochloric acid might turn these amines to harmless chlorides, and certainly the first case to which the acid had been given had greatly improved. The medical profession should realise that many "remedies" for nephritis were futile where they were not actually harmful.

Dr. Lewis Glover said that during the years 1918–1925 906 urine analyses had been done on his patients, and among these 60 males and 90 females had shown some albuminuria. Apparently all these examinations had been useless, and practitioners might as well save their time and their patients' money. Clinical observation had taught him that a small amount of albumin was of no value as an indication of the patient's condition.

Dr. Lewis Smith wondered whether we were not assuming more than we had a right to assume, and whether the present way of investigating nephritis was not too chemical. The kidney was a living substance, not a test-tube to fill up with drugs, which might or might not leak through. We had to ask why some cases get well and others do not. It was still possible that the kidney had an internal secretion. Many years ago he had found that treatment by glycerinated extract of kidney substance gave good results in some cases. He had seen cases a great deal worse for the Epstein treatment, and deplorable results from decapsulation. The skin was a very valuable and often neglected means of helping to relieve the kidney. In his opinion, cases of acute nephritis were better with a milk diet which contained very little protein and some carbohydrate.

Dr. A. Bousfield said that he had seen no case of acute nephritis in his practice; it was almost non-existent, because people were taken so much care of in general practice. Yet he had large numbers of cases of pyelitis, cystitis, and chronic renal disease. The prognosis was extremely difficult. It was important to be sure that the albumin came from the kidney and not from the pelvis or bladder. He had known very acute cystitis follow an overdose of rhubarb and claret, and it was surprising how difficult it was to damage the kidneys; they seemed to be much more resistant to toxic materials than other parts of the urinary tract. That he had had only two fatal cases in the influenza epidemic he ascribed to the routine administration of sodium citrate and sodium phosphate; it had been noted that the fulminating cases in soldiers had had a very acute nephritis; perhaps these two drugs had saved the patients by preventing the nephritis. The treatment of nephritis was preventive rather than curative.

Dr. R. S. Allison said that at Ruthin Castle the type of case was rather that of general practice than of hospitals, the somewhat vague and early case of middle age with headache, giddiness, and gastro-intestinal disturbances. The blood pressure was high, and there would be a trace of albumin. They had been getting satisfactory results with Calvert's modification of Prof. MacLean's urea-concentration test. In this 15 g. of urea were given at bedtime and the urine collected until 7 next morning, when 2 pints of fluid were given and its excretion then observed for two hours. This gave a range between the maximum and minimum concentration which was useful in cases where the simpler test gave anomalous results. In borderline cases there was often a fairly good excretion of urea, but a difference in the diuresis after drinking, the percentage of urea in this stage being distinctly higher than in normal controls. When the two-hour period was extended to four hours it was found that it was a matter of delay in the time of excretion of the water, for the urea concentration fell markedly in the second two-hour period. This might prove a significant point in the detection of fine degrees of renal impairment. He was convinced that enlarged tonsils and adenoids were an important ætiological factor of nephritis in children.

The President said that the prognosis of acute hæmaturic nephritis in children was good; it was a condition that was cured permanently if it was cured at all.

Dr. Arthur Ellis said that where the acid-ammonia ratio was equal the patient was more liable to nephritis than when the ammonia preponderated. The alkaline type was much more liable to sepsis than others, and the kidney might be infected that way rather than through the strain of excretion. He had found magnesium sulphate injections useful in getting the kidney to work; they produced a rapid and efficient emptying of the intestine, and this took a considerable strain off the kidney. For some unknown reason the addition of a hundredth of a grain of physostigmine to the injection led to a very rapid unloading of the œdema.

Reply.

Prof. MacLean, in reply, said that the unanswered question was why two apparently identical cases went different ways, one clearing up, while the other went on to a chronic condition. If the general practitioner could not in some measure use what had been discovered in the laboratory or hospital, then, in his opinion, the investigations were a comparative failure. The Epstein diet, or any régime which included a large amount of fat, meant more fat in the blood, and there was some evidence for the possibility that the œdema tended to be more permanent when there was much fat in the blood. The truth was that very little was known about kidney disease.

SECTION OF BALNEOLOGY
JOINTLY WITH THE
INTERNATIONAL SOCIETY OF MEDICAL HYDROLOGY.

THE TREATMENT OF RHEUMATISM IN INDUSTRY.

A JOINT meeting of these two bodies was held at the Royal Society of Medicine on Nov. 27th, the chair being occupied by Dr. **GUSTAVE MONOD** (Vichy), the President of the International Society, whose aim, he said, was to bring to bear on such subjects as the one to be discussed to-day—chronic rheumatism—the strength which internationalism gave to every question they dealt with. In France the general hospitals were not open to these cases, and the only opportunity open to the people for institutional treatment of them was to attend the thermal hospitals. And as the general hospitals of Paris did not publish statistics concerning rheumatism, it was difficult to know the degree of its prevalence.

National Loss by Rheumatism.

Sir **GEORGE NEWMAN**, Chief Medical Officer of the Ministry of Health, expressed on behalf of the Minister cordial congratulations to the Society and the Section on the efforts they were making to grapple with this formidable and protean disease. Through the channel of Government a survey of the incidence of rheumatism among the insured population of this country had been prepared. He had always felt that the first business was to endeavour to measure its prevalence and its gravity in order that all effort should be properly focused and directed. It was necessary to measure and gauge the problem before it was grappled with; there was a tendency, in all nations, to apply remedies without sufficiently careful diagnosis. In this country an effort had been made to measure both the condition which had to be met and our shortcomings in meeting it. The subject to be considered to-day was chronic non-articular rheumatism, such as was manifested in fibrositis, muscular rheumatism, sciatica, &c., and in the second place the form seen in chronic arthritis. In this country, said Sir George Newman, we were losing—or we were spending in benefit much of which was lost—£2,000,000 per annum in this group of disease, and among the insured population of 14 millions, time equal to 3 million weeks, or 60,000 years, per annum. This amount of invalidity was recognised by the Government as an equally serious burden on the State to that caused by such other diseases as cancer and tuberculosis. There was thus need of active organised treatment, as at present it was quite inadequate; in all countries this particular problem should be tackled.

Means of Dealing with the Disease.

What, Sir George Newman asked, was the sound way of grappling with this disease group? He felt sure it was necessary for greater care to be exercised both in discovery of the cause of the infection or the metabolic change in each case, and in regard to its removal. The old idea of making a frontal attack and dealing with the palpable and obvious was neither scientific nor effective; the profession must face and deal with the foci of infection. This meant, above all else, team-work, various experts combining in hospital to deal with the focus which came into their particular specialty—physician, dentist, radiologist, laryngologist, bacteriologist, surgeon. The second aspect of the combat against this group was the raising of the resistant and reactionary powers of the body. Measures must include thermal, electrical, hydrological, massage, and, indeed, any kind of treatment which would place the body in the best position to make its own great answer. It all came back to the question of the seed and the soil. A third point concerned the handling of the evidence of this morbid process as it represented itself in childhood. A beginning must be made at whatever age the disease process first affected the body. The riddle of end-results could not be answered unless the principles of preventive medicine were applied in childhood also. Rheumatism did not enter into death certification in the same way that other well-known scourges entered, and it must be recognised that this disease group formed a national problem in public medicine.

As regards institutions for treatment, to begin with we had, said Sir George Newman, three or four great spa hospitals, all of which could be used to advance the treatment of this disease. At the Ministry of Health arrangements were being sought by which there could be established an arthritis unit, in which diagnosis, treatment, and prevention could all be represented; and the Ministry hoped that one result of this meeting to-day would be to afford some guidance in this respect.

Holland.

Dr. J. **VAN BREEMEN** (of the Institute for Physical Treatment, Amsterdam) said the report of our Ministry of Health was an exemplary piece of pioneer work, and Holland had nothing to offer on parallel lines. The number of rheumatic patients in Holland was very large, but the scientific study and social means of combating the disease was still in its infancy. Chronic rheumatic symptoms were stubborn non-purulent inflammations of joints, muscles, nerves, and subcutaneous tissues, typical painfulness, and great susceptibility to cold, moisture, and draughts. Four factors must always, he contended, be kept in view: (1) special foci such as in tonsils, teeth, and appendix, or such general conditions as influenza; (2) the constitution, with its tendency to a rheumatic diathesis; (3) derangement of the circulation in the skin; and (4) external circumstances—climate, intoxications, traumata, excessive fatigue. Before instituting treatment each case should be very thoroughly examined. His method with his patients was to first give general treatment directed to improving the circulation, the metabolism, and the state of the nervous system—i.e., by means of baths (steam, hot air, and electric light), douche-massage, and mercury lamp. Next he applied diathermy, local hot air, light baths, and massage as local measures to improve the function of the joints. The form of arthritis known as "rheumatoid tuberculeux" needed actino-therapy, plenty of rest, good food, arsenic, and salt baths. Heroic measures such as strong bath cures or strong steam baths were often injurious here. For arthritis of larger joints he regarded diathermy as of great importance. High-frequency currents often greatly relieved the sufferings of people with a pronounced arthritic diathesis. His view was that the more definite and severe the arthritic diathesis the greater was the influence of diet. This should be sparing, especially in the matter of albumin and carbohydrates. But in rheumatoid tuberculeux a fatty diet was indicated.

It was necessary for the better prevention of invalidity that there should be a wider application of physical treatment and baths, and the skin should be specially studied. There should also be set up clinics and laboratories for conducting a methodical research into this disease group, and it must be recognised that a distinctive manifestation of rheumatism was associated with each occupation. He advocated the formation of an international committee for a large organised effort to combat chronic rheumatism.

Denmark.

Dr. **HANS JANSEN** (Copenhagen) said he included under the term rheumatism all the affections which Sir George Newman embraced in his report of 1924, and urged the importance of getting established an international uniform nomenclature in this branch of medicine. A year ago he, the speaker, pointed out in his country the need for setting up special hospitals for treating these diseases. In Denmark rheumatism accounted for 58,000 sick days per annum; and there were, among men workers there, 42,000 cases of that disease. At the end of 1923, 7237 people were declared to be totally invalided by it, and

14 per cent. had some form of chronic arthritis. There were, in his country, six or seven private sanatoriums where these conditions could be treated, general hospital cases being chiefly acute ones. In 1923, 3000 subjects of rheumatic disease were treated in Danish institutions and privately, but no Government agencies were at work on the subject. The poor were treated entirely free of expense, liberal grants being made towards the cost. It was the impression of himself and his colleagues that a cold and damp climate induced a considerable part of these diseases. Investigation had been made into the subject, including the effects of X rays and radium.

Sweden.

Dr. G. **Kahlmeter** (Stockholm) said that there were no exact statistics as to the incidence of rheumatic diseases in Sweden, but, next to old-age infirmities, articular rheumatism was the most serious cause of invalidity. 9·1 per cent. of all cases of permanent invalidity were due to chronic articular rheumatism, the next highest figure being 5·8, pulmonary tuberculosis. For treatment there were available in the country about 50 spas (during the summer), the institutions for medical treatment set up by the Board of Pensions, and the general hospitals. The spas, however, were not large or modern enough, and were only available during two and a half months in the year. The institutions organised by the Board of Pensions were intended to prevent disablement, and treatment was arranged for all rheumatic diseases and neuroses; they embraced 350 beds. Patients usually remained in them from two to three months, and if necessary had dental and orthopædic care, while some who needed it were taught another trade. Two-thirds of the cost at these establishments was paid by the Board (i.e., the State) and the remainder by the patient. Only patients were taken in who offered some prospect of again becoming self-supporting. The hospitals of the country were only intended for acute cases. Coöperation was of the greatest importance to ensure success in the treatment of these diseases, and the great need in Sweden was for a central arthritic hospital in Stockholm in association with the university clinics, especially for the facilitation of research. This would be one of the great objects of the newly constituted committee for combating rheumatism, of which the speaker was secretary.

Great Britain.

Dr. R. **Fortescue Fox** said many were of the opinion that the kind of cases under discussion were becoming increasingly prevalent. In the case of chronic rheumatism the profession was dealing with sick persons who were not, as a rule, hospital cases, but were cases who could be treated in out-patient departments, or special clinics, and at the spas and health resorts of the country. It was a very difficult matter to apply the physical remedies with the best effect; these cases had to be treated from many sides. Large numbers had an infective element, which ought to be removed if it could be discovered. Other methods which presented themselves were vaccines, thyroid treatment, and drugs. It was certainly a disease of cold and damp climates, and much could be done to counteract the ill-effects of climate by the right use of waters and baths. The claim which had been made that all the British spas could treat chronic rheumatism with success he regarded as a just one. They all had in common one important agency, well-appointed bathing establishments. In a large proportion of cases one could provide effectual and successful treatment by external methods alone, as given under medical direction and with proper skill. It was now clear that a condition of extraordinary sensitiveness underlay the rheumatic state, and in using heat and cold in rheumatic cases one was working with edged tools. He had seen excellent results, but he had also known many failures due to want of knowledge and care. It was very desirable that the benefits due to external treatment at spas should be made available in the towns. Was this work best done in connexion with hospitals, or ought there to be set up rheumatism clinics? In favour of the latter was the fact that intensive study and a proper grouping of maladies could be carried out, and there could be a liaison with institutions which were conducting special research. In such clinics there must be a whole-time expert medical director, with a suitable linkage with research establishments.

Dr. R. L. J. **Llewellyn** pointed out the gravity, from the national health standpoint, of the recent report of the Ministry of Health on the prevalence of rheumatic diseases in this country. Nothing could so raise the resistance of people to rheumatic infection as the discriminating use of hydrotherapeutic procedures, and there was need for these in the case of people employed industrially in the large centres of population. In Great Britain there were between 45,000 and 50,000 children of school age with rheumatic heart disease. Recently in a children's hospital in London it was found that out of 172 cases of rheumatic fever 66 per cent. developed heart disease; 22 of the 172 died and 38 were permanently invalided. One in every five of the population living at the age of 10 would, on the figures collected, succumb to organic heart disease. A campaign against rheumatic diseases similar to that against tuberculosis was much needed.

Dr. M. B. **Ray** said the yearly number of people in Greater London who were likely to seek advice in respect of rheumatic diseases was 60,000. In England and Wales some 372,000 suffered from some form of rheumatism. Not all cases of non-articular rheumatism required treatment other than could be given by the general practitioner. It was, he thought, safe to say that in the London district alone there were 22,000 insured persons who were likely to benefit from more enlightened treatment; a certain number needed in-patient care. Moreover, satisfactory research into causation could only be carried out if patients were constantly under observation.

Switzerland.

Dr. F. **Kornmann** (Ragaz) said the treatment of these cases in Switzerland was available for both the well-to-do and the poor, the latter being assisted by grants from private bodies and from Government endowments. A large proportion of the cases in the country came from Geneva and places on the shores of the lake. The methods of treatment were electricity, baths, ionisation, massage, and protein therapy. Slight and early cases were often entirely cured, chronic cases were sometimes improved, but sometimes these latter proved intractable.

Roumania.

Prof. **Theohary** (Bucharest) said cases of arthritic and chronic rheumatism were treated at four spas in the main, other spas being mud and strong brine ones. Four classes of cases received some form of assistance—namely, civil servants, employers in small industries, labourers, and soldiers and the very poor. The last-named were treated in the sanatoriums organised by the Red Cross. Public bodies in the country were now subscribing increasing amounts to help those among the poorer population who stood in need of spa treatment for chronic ailments.

Spa Treatment.

Dr. **Kerr Pringle** said that seven hydropathic hospitals in this country were entirely devoted to the treatment of these conditions. At Bath the largest hospital had 136 beds, with 1200 patients, while a small one had 10 beds. The Devonshire Hospital at Buxton had 300 beds and 4000 rheumatic cases. St. John's Hospital, Droitwich, had 30 beds with 603 annual cases. At Harrogate the Royal Bath Hospital had 150 beds and 2500 cases. Strathpeffer had 15 beds, and 80 or 90 cases under treatment, while at Woodhall Spa there were 30 beds available for this disease and 188 cases. At all these institutions there were considerable waiting-lists, and many cases yearly had to be refused admission. In Harrogate last season 140 cases had to be refused as unsuitable, without even seeing them. In Bath 12 per cent. of the men had osteo-arthritis, 6·9 per cent. women, while in Buxton the proportions were 6·6 per cent. men, 8 per cent. women. The Ministry of Health figures gave 8 per cent. in men, 9 per cent. in women. He contended that no case should be labelled one of osteo-arthritis unless a verification had been reached by means of X rays. An important matter to be taken into consideration was the environment of the patient. For rheumatic cases the most useful type of bath was the massage-douche, and the paraffin-wax bath at Harrogate had proved distinctly useful in certain types of cases. With regard to results, he said it was difficult to state these in figures. In cases of fibrositis and neuritis good results would be seen within a few weeks of the patient leaving the hospital; but in chronic joint cases it might be months before it could be said that there were definite results, and even then it was a question of degree. Patients' reports on their own condition were well known to be worthless.

Dr. CHARLES W. BUCKLEY spoke of rheumatic disorders in industry in the light of the experience he had gained as physician in the largest mineral water hospital in the country (the Devonshire Hospital), one which dealt with 4000 patients per annum drawn from the industrial classes. These cases among workers could be divided into four groups. In the first group were cases of rheumatic fever with its sequelæ, which might require long treatment, but for which any well-equipped institution would suffice. The second group embraced fibrositis of muscles, nerves, or joints, a group which reacted better to spa treatment than to any other, though some might require continued massage or other physical treatment, and attention to hygiene and diet after returning home. Thirdly, there were the cases of rheumatoid conditions. Many cases were now being sent to spa hospitals who were suffering from chronic osteo-arthritis of such degree as to be incapable of material improvement, and were occupying beds which could be used to greater advantage. Home treatment, where the services of a nurse skilled in massage could be obtained, was best for these, with such orthopædic treatment as could be made available under some scheme. His fourth group were the gouty, and these, he said, reacted more effectively to treatment at a suitable spa than to any other method, and this would definitely reduce the frequency, the severity, and the duration of attacks. The three principal measures required for these diseases were, first, those directed to the cause of the disease. This might be infective, or metabolic, or traumatic; sometimes the cause was dual. Attention to defective elimination was valuable in metabolic and toxic cases. Secondly, there were measures directed to increasing the patients' powers of resistance, by diet, tonics, and the improvement of home conditions. The third class of measures was the most difficult to obtain for the majority of patients—namely, those aiming to remove disabilities and their associated pain. These could only be satisfactorily secured for the industrial classes at present at the spa hospitals, but much might be done elsewhere under a well-organised scheme. Dr. Buckley proceeded to recount the chief advantages possessed by the great spa hospitals for the treatment of the conditions under discussion. There was a need for the education of the public concerning the causative factors and the importance of early treatment; also medical practitioners required more training in the recognition and treatment of ætiological factors. He also advocated the setting up of "rheumatic clinics," where facilities for various examinations could be provided and where the doctor could have consultation over his difficult cases. He felt doubtful as to the possibility of establishing hydrotherapy on any scale, save at the largest centres, though he was convinced of its value. The great need of the moment, he said, was that a skeleton scheme should be devised and put into force, either by the Government, the approved societies, or some other body. Perhaps no more worthy object existed for the activities of the Red Cross Society.

Discussion.

Mr. W. A. APPLETON, an official in the trade-union movement, said his organisation found that 6 to 10 per cent. (varying according to occupation) of the sickness among the workers was due to this disease, and he believed the actual amount of disability among artisans was really much greater than those percentages indicated. There was a need for unified action on the matter, and he would be glad if medical men would talk over the situation with those who were intimately concerned with the industries of the country. People expected the State to do everything, but the State moved slowly.

Dr. MAX BERG (Berlin) expressed the hope that some day Germany would join the League of Nations, and remarked that it would be a great advantage if his country was permitted to join this Society for the scientific study of hydrology, a subject which his countrymen were known to have furthered in a definite degree.

The PRESIDENT thanked the various speakers for their contributions, and expressed the hope that the Section of Balneology of the Royal Society of Medicine would show an active interest in the concerted effort being made to deal with these widespread conditions.

An informal conference in furtherance of future lines of action was held in the afternoon.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.

AT a quarterly meeting of this Association, held in the rooms of the Medical Society of London on Nov. 17th, Sir FREDERICK MOTT, the President, in the chair, Dr. JOHN CARSWELL read a paper entitled

Insanity and Crime: Some Suggestions Arising out of the Atkin Report.

It could, he said, be taken that, at least in form, the McNaghten Rules had received such fresh support as to preserve them in being for another generation. Yet the medical profession would not admit that the controversy was ended; indeed, there seemed a desire for adjustment of the medical and legal points of view. The rule recommended by the Atkin Committee read as follows:—

> "It should be recognised that a person charged criminally with an offence is irresponsible for his act when the act is committed under an impulse which the person was by mental disease in substance deprived of the power to resist."

The committee added: "It may require legislation to bring this rule into effect," and later, "We have no doubt that if this matter were settled, most of the criticisms from the medical point of view would disappear."

Members of the Association, Dr. Carswell said, would acquit themselves as medical men acquainted with the clinical aspects of disorders of mind of expressing their ideas as to what they might regard as the test of criminal irresponsibility in these terms, which were lawyers' terms, and indeed, all the trouble had arisen in that way. Did the accused know what he was doing? And if he knew, did he know that it was wrong? These were the formulæ framed by lawyers, and the psychiatrist had no responsibility for them. Fitzjames Stephen, in his "History of the Criminal Law," Vol. II., p. 174, after considering Maudsley's observations, said:

> "I understand by the power of self-control the power of attending to general principles of conduct and distant motives and of comparing them calmly and steadily with immediate motives. Diseases of the brain and the nervous system may cause definite intellectual error, and if they do so, their legal effect is that of the innocent mistakes of fact. Far more frequently they affect the will by either destroying altogether or weakening to a greater or less extent, the power of steady, calm attention to any train of thought."

Dr. Carswell went on to say that a series of cases in recent years were available to show that judges had charged juries in the sense indicated, and even in the much debated Ronald True case Justice McCardie left three questions to the jury; the first two were in the terms of the McNaghten Rules, and the last was expressed in these terms:

> "Even if the prisoner knew the physical nature of the act, and that it was morally wrong and punishable by law, yet was he, through mental disease, deprived of the power of controlling his actions at the same time? If yes, then, in my view of the law, the verdict should be 'Guilty but insane.'"
